Pyrolytic oil (Pyro-oil/bio-oil) is yet another example of a diesel substitute that finds its effective application in the diesel engine. The extensive sources of pyro-oil are waste tires and plastics which have effectively controlled the solid waste management problems. Pyro-oil showed promising engine performance when blended with diesel/gasoline up to 15–20 vol% in

Table 1 Impact of methanol blending with gasoline on fuel properties, engine performance and emission attributes

Blend with gasoline vol%	Impact on engine emission	Impact on engine performance	Remarks	Citation
10 and 20	1. Lessens particulate matter emission. 2. Lower exhaust gas temperature. 3. Higher HC emission at lower engine loads	1. High cylinder pressure due to good methanol combustion. 2. Lower heat release rate of blends 3. The duration for combustion of blended fuel was higher. 4. Higher BSFC due to lower calorific value.	1. Lower heating value of methanol (20 MJ/kg) compared to gasoline (44 MJ/kg).	Agarwal <i>et al.</i> (2014)
3, 5, 7	1. Reduction in CO emission. 2. Lower HC emission	1. Higher volumetric efficiency of methanol due to higher latent heat of vaporization 2. Lesser output power due to lower heating value.	2. Addition of excess methanol provokes the emission of unburned CH₃OH	Elfasakhany (2015)

compression/spark ignition engines. This alternative fuel has the capability of reducing GHG emissions and deliver similar engine performance as conventional diesel.

Therefore, the present article emphasizes on application of different green fuel alternatives/additives that can be effectively blended with conventional gasoline and diesel in improving the fuel properties without any engine modifications. The survey also meticulously investigates the efficacy of these additives in mitigating the adverse effects of petroleum fuel on global climate.

Effect of Alcohol Blending on Gasoline and Diesel

Bio-Methanol Blending

Gasoline-bio-methanol blend

Bio-methanol (BM) acts as an alternative chemical to conventional gasoline that can reduce the consumption of fossil fuel and has also beneficial effects on the environment because of its low carbon emission. The octane number of 5% BM and 95% gasoline (BM5) is 98 which make BM5 almost equivalent to the neat fuel with respect to engine performance while providing reduced emission of harmful pollutants (e.g., CO, HC, PM); however, the brake specific fuel consumption (BSFC) is higher compared to neat gasoline.

Moreover, the performance and cost analyses indicated that BM5 could substitute neat gasoline and was comparatively more environment-friendly (lower reactivity of the organic emissions) and cost-effective than conventional gasoline. **Table 1** illustrates the effects of methanol-gasoline blending on SI engine emission and performance. The addition of methanol has immensely influenced the SI engine performance and has also controlled the harmful emanations of GHGs. BM demonstrated superior performance in terms of CO and HC reduction due to the higher oxygen content of the fuel. Again, greater methanol blends facilitated lower NO_x emission. Nevertheless, excess methanol deteriorates the heating value of the fuel which causes late burning of the fuel and increases BSFC and lowers brake thermal efficiency (BTE).

Also, it exceeds the unburnt methanol emission, therefore; excess methanol (85% methanol) should be avoided in consideration of gasoline-methanol blending.

Diesel-bio-methanol blend

The high oxygen content of BM has also favored its use as a green diesel fuel blends in CI engine. **Table 2** describes the behavior of diesel-methanol fuel blend in CI engines.

It could be observed from **Table 2** that the addition of methanol has effectively reduced the GHG emission in comparison with neat diesel. However, similar difficulties (as in gasoline-methanol blend) were also faced in the diesel-methanol fuel blend. At higher methanol proportion, decreased cetane number reduces the calorific value of the fuel that causes the deterioration in the engine performance.

Recent practices in bio-methanol blending

Current practices (**Table 2**) enumerate the addition of long chain alcohols to the diesel-methanol blend that can increase the capacity to hold water, thereby improving the stability of the blended fuel (Chen *et al.*, 2019). A similar technique for the improvement of gasoline-methanol blended fuel can also be effective. Since lower carbon alcohols are not completely miscible in conventional fuel owing to phase separation issues in presence of water; therefore, the addition of branched-chain alcohols to gasoline-methanol blend would make the overall blend more homogeneous. The branched alcohols viz. isobutanol has been observed to be as less polluting fuels with smooth operational capability due to nullification of separation problem of gasoline-methanol blend (GMB) in presence of water. Furthermore, the leaning effect on addition of alcohol can appreciably facilitate combustion behavior of the fuel (Elfasakhany, 2018).

Table 2 Effects of alcohol blending on diesel properties, engine performance and emission profiles

Blends	Impact on engine emission	Impact on engine performance	Remarks	Citation
Methanol and Diesel	1. Alcohol content reduces exhaust gas temperature. 2. Higher methanol content above 30% results increase in THC emission. 3. 80% reduction in CO emission. 4. High NOx emission with increase in alcohol blend.	1. Above 25% blend result in substantial ignition delay. 2. Increase in heat release rate. 3. Above 30% load results in reduction of in-cylinder pressure	1. Lean fuel decreases NOx emission but deteriorates engine performance. 2. Presence of water increases the immiscibility of methanol in diesel. 3. Higher blends lower the cetane number and heating value of fuel thereby reducing ignitability.	Jamrozik (2017)
Diesel, Methanol and n-pentanol	Lowers soot emission and increases NOx emission.	Shortens combustion duration.	1. Presence of long chain alcohols in diesel-methanol blend increases the stability and solubility of methanol in diesel. 2. Increases the heating value of the fuel.	Chen <i>et al.</i> (2019)

Bioethanol Blending

Diesel-bioethanol blending

European Parliament Directive (2009/28/EC) passed a regulation of using 10% of renewable green fuels in transport by 2020. Bioethanol (BE) amongst the common renewable fuels has gained major attention due to its positive influence in lowering NOx emission (Park *et al.*, 2012). However, from the exhaust emission analyses presented in Fig. 1(A and B), the blending of BE beyond a proportion has least impact on the CO emission (Fig. 1(A)) while it aggravates HC emission (Fig. 1(B)). The higher values of HC emission may result lower cetane number (value 11) that extends the ignition delay, eventually rendering decomposition of the blended fuel (Tutak *et al.*, 2017; Jamrozik, 2017) in engine bore. Notably, the lower NOx emission at higher BE blends (Fig. 1(C)) is due to the leaning effect during the air-fuel premixing prior to its induction into cylinder of CI engine for combustion.

Another usual problem related to the engine exhaust of petroleum diesel is the high emission of particulate matter (PM)/soot, which causes severe health damages. To regulate PM, engine modifications involving diesel particulate filter can be considered; however, these kinds of additional facilities increases the manufacturing cost of the diesel engine. In this context, BE provides an immense benefit as blending stock for diesel owing to its capability in retarding soot/PM emission.

Table 3 describes the soot/PM emission values for diesel blended with different proportions of BE. It could be observed in a study conducted by Lee *et al.* (2018) that with the application of BE in diesel, the size distribution of PM decreases from 1000 nm to 50 nm which advocated for the beneficial effect of blending BE with diesel. Nonetheless, from the aspect of the engine performance, bioethanol blended diesel resulted in higher exhaust gas temperature, lower combustion duration of 22° and lower thermal efficiency due to a lower calorific value that restricts the use of bioethanol at higher blend percentages.

Gasoline-bioethanol-gasoline (GBE) blending

BE blended gasoline also serves as an important green fuel substitute that is capable of providing improved brake power and higher thermal efficiency in SI engine. The octane number of 30% BE blend was reported 13% higher than that of neat gasoline (Costagliola *et al.*, 2016) indicating compatibility of BE as a suitable green blending component for gasoline in SI engine.

Notably, the oxygen content of bioethanol is 35% which renders lower PM emission ($1.7 \times e^{12}$) during the combustion of GBE fuel. Other properties e.g., lesser flame luminosity and lower vapor pressure make it efficient during cold start-ups of the engine. It has been also observed that for higher BE blend percentage; the fuel consumption remains identical to gasoline during cold condition; whereas, fuel consumption increases at warmer ambient with an increase in BE proportions. Yet another important aspect of BE as represented by Fig. 2, is the reduction of exhaust emission of the engine including NOx, CO and HC. It has been reported (according to Worldwide Motorcycle Emissions Test Cycle, Costagliola *et al.*, 2016) that increase in BE blend could substantially reduce HC and CO emissions; however, an enhancement (nearly 40%) in NOx emissions may be observed with respect to the engine types having different kinds of fuel injection systems (carburetor/electronic multi point fuel injection).

LCA case study for GBE blending

LCA and environmental life cycle costing assessments have been illustrated in this article to give a clear concept about the sustainability of BE (wheat straw/corn stover derived) use as a green additive to gasoline. The case study was based on the emission profile/km of a middle sized passenger car (Daylan and Ciliz, 2016). The study was conducted 'from cradle to grave' perspective considering parameters viz., feedstock acquisition, BE/gasoline production and fuel blending with fuel storage. LCA for GBE10, GBE85 and G100 blends demonstrated that with increase in BE blend, GHG emissions including CO and CO₂ could be considerably reduced from 522 mg/km to 341 mg/km and 0.273 kg/km to 0.129 kg/km respectively. Similar results were also observed for SO₂ discharge where the emission values mitigated from 420 mg/km to 227 mg/km. However, the NOx emission was found to increase by 19.7% and fuel economy was decreased by 24% in case of GBE85 compared to G100. Besides, LCA study has

Fig. 1 Exhaust emission analyses of bioethanol blended diesel.

Table 3 Soot emission from CI engine using bioethanol blended diesel

Blend combination	Engine condition	Soot/PM emission	Reference
Ethanol (20)	Speed: 1200 rpm	D100: 0.05 g/kWh	Park et al. (2012)
Diesel (80)	Engine Pressure: 40MPa	E20: 0.025 g/kWh	
Ethanol (50)	Speed: 1000 rpm	Reduction in PM molecules during combustion.	Lee et al. (2018)
Diesel (50)	Engine Pressure: 0.8 MPa		

Fig. 2 Exhaust emission attributes from SI engine using bioethanol blended gasoline. Reproduced from Costagliola, M.A., Prati, M.V., Murena, F., 2016. Bioethanol/gasoline blends for fuelling conventional and hybrid scooter. Regulated and unregulated exhaust emissions. Atmospheric Environment 132, 133–140.

also concluded minimal stratospheric ozone layer depletion for GBE85 compared to GBE10 and G100 due to lower GHG emission from GBE85.

This study therefore infers that GBE85 has significantly lower environmental impact (global warming, ozone layer depletion, acidification, crude oil consumption) compared to G100 and GBE10. Again cost assessments for GBE85 results in 23% lower driving costs for in road transports which also advocate its economic sustainability over conventional gasoline.

However, BE blending above a threshold limit possess certain considerable drawbacks. The inclusion of BE as blends with gasoline above a specified threshold limit generates another spectrum of emissions involving acetaldehyde, VOCs, formaldehyde, benzaldehyde and significant levels of vaporized ethanol during combustion. Acetaldehydes are known for provoking respiratory irritation, bronchitis and asthma; while, benzaldehydes were considered as nerve toxins which could cause nerve failure and brain impairment. Formaldehyde is also associated with the carcinogenic effects on human body. Therefore, the release of such toxins with the exhaust emanation can cause serious damage to the human health and environment which restrains its use as a neat fuel in SI engine.

Fig. 3 Effects of butanol addition on diesel engine emission at 30 Nm load and 60° BTDC. Reproduced from Yun, H., Choi, K., Lee, C.S., 2016. Effects of biobutanol and biobutanol–diesel blends on combustion and emission characteristics in a passenger car diesel engine with pilot injection strategies. *Energy Conversion and Management* 111, 79–88.

Biobutanol Blending

Biobutanol blending with conventional fuel is another pollution reduction approach which could be competently used in both SI and CI engines without any engine modifications. The higher heating value of butanol (18.46%) renders reduced specific fuel consumption in engine compared to ethanol. Additionally, the higher knock resistance characteristic of butanol has helped improving the ignition timing resulting in more efficient combustion of the blended fuel. The leaner fuel/air ratio and higher oxygen content are further contributor to better burning of the fuel (Feng *et al.*, 2015).

Gasoline-biobutanol (GBu) blending

To explain the influence of biobutanol (Bu) addition in gasoline, an example has been cited from the work of Feng *et al.* (2015). The experimental investigation demonstrated that within the speed range of 2500–8500 rpm, an increase in Bu percentage from 30 (GBu 30) to 35 (GBu 35) vol% has curtailed the unburnt HC emission (3750–2600 ppm) compared to pure gasoline. The improved combustion efficiency, lower carbon content and higher air-to-fuel ratio were the reasons behind the suppression of HC emission. Moreover, in this study, CO emission was also reported to become reduced from 8×10^4 ppm (neat gasoline) to 5×10^4 ppm (GBu 35). The aforementioned reasons holds good in this case also. Unfortunately, NOx emission has a completely reverse scenario. An increase in Bu blend led to augmented NOx emission to 2000 ppm from 1000 ppm. The higher residence time and combustion gas temperature along with greater oxygen content contribute to more NOx emission according to the Zeldovich mechanism.

Diesel-biobutanol (DBu) blending

Bu showed similar blending efficacy when mixed with conventional diesel. The higher oxygen concentration in Bu (2.34 times more) compared to diesel prompted the clean burning of the green fuel. Even biobutanol blend is also efficient in impeding PM and nano-level particulate emission.

To explain the fact a reported work by Yun *et al.* (2016) may be considered wherein 10% and 20% Bu was premixed with diesel for a passenger car engine running at a speed of 1500 rpm with a varying load of 30 Nm and 60 Nm and the pilot injection timing has ranged between 20° and 60° before the top dead center (BTDC). It could be observed from Fig. 3 that, addition of Bu could lower the NOx discharge by virtue of maintenance of lower gas temperature in the burning chamber and higher ignition delay of the blended green fuel.

Similarly, soot formation could also be hindered by increasing Bu proportion in blended fuel at higher load while identical values were recorded at lower engine load (30 Nm). CO emission was greatly reduced with an increment in butanol content which could be ascribed to the leaning effect of Bu rendering such improvement. However, HC emission depends differently on several factors:

- Fuel Quality: Extended ignition delay; inferior cetane number and high heat of vaporization.
- Engine Attributes: Geometry of the combustion chamber; wall wetting of engine cylinder and engine piston surface.

Table 4 Properties of biodiesel obtained from different edible oil feedstocks

Feed stock	Oil content (%) ^a	wt% fatty acid	Name	Pour point (°C)	Cetane no
Canola oil, <i>Brassica campestris</i>	35	56.6	C18:1	−7	61.5
Mustard, <i>Brassica juncea</i>	30	20.5	C18:2	5	53
Soybean, <i>Glycine max</i>	21	53.7	C18:2	−4	46
Palm kernel, <i>Elaeis oleifera</i>	40	56.1	C18:1	10	56.5
Palm olein		41.9	C18:1	7.22	62
Palm stearin		61.1	C16:0	13.48	74.3
Sunflower, <i>Helianthus annuus</i>	44–51	56.5	C18:2	1	49
Corn, <i>Zea mays</i> (germ)	40–50	44.7	C18:2		
Olive, <i>Olea europea</i>	55–83	71.6	C18:1	2	
Coconut, <i>Cocos nucifera</i>	63	50.9	C12:0	−8.47	45–55
Ricebran, <i>Oryza sativa</i>	14.7–19.10	38.9	C18:1	5.8	
Groundnut, <i>Arachis hypogea</i>	36–56	41.1	C18:1		54
Sesame, <i>Sesamum</i>	44.6–53.1	41.2	C18:2	18	38.2

Note: Issariyakul, T., Dalai, A.K., 2014. Biodiesel from vegetable oils. *Renewable and Sustainable Energy Reviews* 31, 446–471.

Furthermore, Bu blended diesel (DBu) demonstrates advantages from the aspect of the engine performance. The DBu exhibited comparable engine performance as that of the neat diesel both at higher and lower injection timing along with higher BSFC and lower EGT under all operating conditions.

Demerits of biobutanol blending

The acrolein emission is a major issue of butanol blended fuels that causes impaired metabolism, edema while longtime exposure triggers cancer to humans. Moreover, Bu is generally produced by biochemical route; and the downstream purification process is cost extensive because of additional by-product formation viz., hydrogen, acetic, lactic and propionic acids, acetone, isopropanol and ethanol etc. Besides, the lower yield of Bu through fermentation makes it more challenging for its commercial application as a green fuel.

Emerging trends

Recent practices involve triple blend i.e., combination of acetone-butanol-ethanol (ABE) which can nullify the individual disadvantages of ethanol and butanol. ABE (10–30 vol%) can be blended both with gasoline and diesel that could effectively reduce CO, NO_x, HC and soot emissions; nevertheless, the flipside of ABE is its lower calorific value that increases the BSFC while higher ABE concentration augments CO and NO_x emissions.

Biodiesel Blending

Biodiesel (B) is made of monoalkyl esters (derived from long chain fatty acids) which can be usually produced by esterification/transesterification reaction of waste/refined vegetable oil and animal fat with short-chain alcohols (methanol, ethanol) in presence of a homogeneous or heterogeneous catalyst (Banerjee and Chakraborty, 2009). The feedstock could be further categorized into vegetable oils (including edible and non-edible oil), animal fats and organisms like microalgae and cyanobacteria (*Cyanobium* sp., *Limnothrix* sp. and *Nostoc* sp).

Notably, biodiesel possesses various positive attributes that can control the emission of harmful GHGs and PM from CI engines. Nevertheless, the biodiesel has to satisfy the American Society of Testing and Materials (ASTM) standard specifications which has been designated as ASTM D-6751 and European standards (EN14214). Therefore, in the following section, the application of biodiesel as green diesel blends has been discussed for mitigation of harmful pollution concerning CI engines.

Edible oil biodiesel: Properties, emission and performance characteristics

Table 4 presents different edible oil feedstocks with fatty acids present in different extents. However, the production of biodiesel using this vegetable oil feedstock chiefly depends on the regional availability. For example, biodiesel production from rapeseed oil was highest in Europe, soybean oil in the USA, palm oil in Malaysia and coconut oil in the coastal areas. Depending on the type of feedstock and fatty acid content, properties of biodiesel viz., cetane number and pour point (Table 4) of fuel vary; this also affects the engine performance and exhaust emission.

Fig. 4 exhibits emission assessments for neat biodiesel derived from four important types of edible oil viz., coconut (CC), soybean (SB), sunflower (SU) and canola (CA); correspondingly, the PM, smoke and NO_x emissions have been compared with that of petroleum-based diesel. It could be observed from Fig. 4 that CC, CA and SB derived biodiesel could effectively reduce the PM discharge whereas SU derived biodiesel has augmented the emission.

Noticeably, CO emission can be reduced in case of all types of biodiesel. Interestingly, NO_x emission has been found to be lesser in SU and SB oil derived biodiesel which was due to higher C18:1 content of the fuel.

Fig. 4 Exhaust emission attributes of biodiesel derived from different edible feedstocks. Reproduced from Rajak, U., Verma, T.N., 2018. Effect of emission from ethylic biodiesel of edible and non-edible vegetable oil, animal fats, waste oil and alcohol in CI engine. *Energy Conversion and Management* 166, 704–718.

Fig. 5 Emission results of diesel-biodiesel (edible oil) blend. Reproduced from Uyaroglu, A., Uyumaz, A., Çelikten, I., 2018. Comparison of the combustion, performance, and emission characteristics of inedible *Crambe abyssinica* biodiesel and edible hazelnut, corn, soybean, sunflower, and canola biodiesels. *Environmental Progress and Sustainable Energy* 37, 1438–1447. Uyumaz, A., 2018. Combustion, performance and emission characteristics of a DI diesel engine fueled with mustard oil biodiesel fuel blends at different engine loads. *Fuel* 212, 256–267.

To further analyze the exhaust features of the diesel-biodiesel blend, a bar chart (Fig. 5) has been constructed, compiling emission results collected from different scientific articles in order to show the proficiency of different kinds of biodiesel. Maximum soot and HC declination were observed in corn-derived biodiesel (CO30) and SU30 showed well depreciation in NOx emanation, while mustard biodiesel (M30) enumerated much lower CO emission (Uyumaz, 2018).

The lower NOx emission in SU30 (Fig. 5) could be attributed to the comparatively higher air-fuel ratio that could suitably regulate the temperature of the combustion chamber, thereby causing lesser NOx release (Uyaroglu et al., 2018). Likewise, the greater oxygen content and higher cetane number were responsible for lower GHG emission. Again, the specific fuel consumption of all kinds of biodiesel was higher than conventional diesel due to higher viscosity and lower heating value; thus, delivering lower brake power.

Nonetheless, it is meaningful to mention that no single kind of biodiesel can control all types of engine emission which require further advancements (such as addition of suitable additives) in order to meet the desired specifications. Moreover, special attention should be given on feedstock selection which must be on the basis of surplus availability, lower production cost and suitable fuel properties with less market demand as edible oil to avoid food-fuel nexus.

Table 5 Properties of different non-edible vegetable oil sources

Feedstock	Oil content (%)	Major fatty acid	Cetane no	Flash point (°C)	Calorific value (MJ/kg)	Non-edibility
Jatropha	35–40	Oleic and Linoleic	57.2–63	238	39.8–42	Contains a toxin, curcin
Karanja	9–46		52–58	187	36–38	Contains toxic flavonoids
Cottonseed	18		41.2–59.5	243	39.5–40.1	Gossypol, a toxic compound
Jajoba curcas	25–30	Arachidic	63.5	292	42.76–47.38	Contains erucic acid
Waste cooking oil	–		60.4	70.6	38.73	Chemical and Physical degradation of oil

Non-edible oil biodiesel properties, emission and performance characteristics

Biodiesel from non-edible oil resources (jatropha, mahua, karanja, cottonseed) has gained immense attention which has effectively reduced the utilization of edible oil feedstock. Reports also revealed that the non-edible oil sources could replace diesel completely in the CI engines (Rajak and Verma, 2018). Besides, waste oil including both waste cooking/frying oil and grease procured from different restaurants, household and food industries also serve as a cost-effective source for biodiesel synthesis.

The research reported in the same study also highlighted the fact that waste cooking biodiesel (WCB) can effectively reduce particulate emission via reducing its mass concentration and mean particle diameter. Further 75% WCB in CI engine showed performance equivalent to conventional diesel, thus advocating its efficacy. Table 5 depicts the properties of some of the non-edible feedstock for biodiesel production. The high flash points and acceptable calorific value make biodiesel appropriate for its use in CI engines.

Furthermore, a review of previous studies has been elaborated in Fig. 6. It can be observed that, NO_x production can be effectively reduced through employment of jojoba and karanja oil derived biodiesel. This is because of higher calorific value and satisfactory air-fuel ratio that can reduce the cylinder bore temperature of the engine resulting in lower NO_x emission. It has been also identified from Fig. 6 that jojoba and karanja derived biodiesel deliver equivalent engine performance similar to diesel in CI engine (appreciable BTE at higher compression ratio). Noticeably, a higher presence of oxygen in cottonseed and jatropha oil derived biodiesel raised the in-cylinder temperature, thereby, rendering complete oxidation with the curtailment of PM, CO and HC emission. Nevertheless lower PM emission has been compromised with a poorer reduction in NO_x emission.

Biodiesel obtained from used cooking oil is also efficient in depreciating CO and HC emissions while marginally higher NO_x emission may result due to faster burning of the biodiesel-diesel blend (Pradhan and Chakraborty, 2018). Other non-edible resources include rubber seed oil, neem tree oil, kusum seed oil, oleander oil which have also found their applications for biodiesel production and can effectively control harmful emission from the diesel engine. Similarly, microalgae e.g., *Calophyllum inophyllum* derived methyl ester (i.e., biodiesel) also acted as a suitable green fuel substitute due to higher cetane number and significant calorific value that facilitated a reduction in NO_x, PM and smoke emission (Rajak and Verma, 2018).

LCA case-study of biodiesel blending

To analyze the economic sustainability and environmental impacts of biodiesel as a green fuel alternative for diesel, LCA serves as the best methodology to find the options for sustainable transport systems. Therefore, a case-study has been considered where biodiesel has been used as fuel for cars, buses and municipal fleets in Greece (Nanaki and Koroneos, 2012). It has been reported that biodiesel (derived from rapeseed oil) fueled cars emit 94% lesser CO₂ while showing equivalent energy consumption of 183.1 MJ/100 km like diesel cars. This signifies lower GHG emission, lessens respiratory impairments and carcinogenic hazards along with reduction in fossil fuel consumption. However, 10% higher NO_x emission has been noted in the study which indicates eutrophication as the major drawback of biodiesel use as fuel alternative. Again, biodiesel production cost is higher which has been accounted for the higher prices of feedstocks that restricts its applications at larger scales. This can be avoided through use of feedstocks available in larger quantities that will not only increase the economic sustainability but will also reduce the environmental impact to the maximum extent. Moreover, suitable fuel additives can be used to substantially reduce NO_x emission while meeting standard fuel specifications.

Animal source derived biodiesel properties, emission and performance assessments

To overcome the cost pertaining to biodiesel feedstock, another alternative that has gained huge consideration is waste animal fats and oils available mainly in densely populated regions. The surplus availability of inedible animal fats has generally been much more compared to waste frying oils globally. In the earlier literature, it has been found that only in the US 2.5 million pounds of waste lipids are generated from restaurants which could be effectively transformed into valuable biodiesel (Rajak and Verma, 2018).

Animal fat resources (Chakraborty *et al.*, 2014) for biodiesel production include:

- Slaughter house animal fats: beef and goat tallow, pork lard, fleshing oil, lamb meat, goat fat and veal stock.
- Poultry farm animal fats: chicken or turkey fat, goose fat; duck tallow and feather meal.
- Waste fish oil.

Rendered animal fats and tallows, fish oil and other waste oil generate renewable and eco-friendly fuels. Again, fish oil generated from different fish processing industries were either discarded or sold at low prices as fertilizers or animal feeds. The optimum utilization of fish oil is in the field of biodiesel manufacturing. Furthermore, the presence of very low or zero toxins like sulfur, nitrogen and other harmful components in fish oil render clean-burning fuel that has also emerged as a cost-effective green alternative for diesel.

Table 6 illustrates the properties of fatty acid esters/biodiesel obtained from different animal sources. The competitive calorific value with diesel, higher cetane number and flash point make such biodiesel appropriate for CI engine. However, it cannot directly replace diesel owing to its higher viscosity and pour point, which would adversely influence engine performance. Again, kinematic viscosity values of some of the esters viz., poultry fat exceeds the limit set by EN14214 which thereby gets rejected as fuel blend in the diesel engine. Therefore, animal fat derived biodiesel has been generally used in the blended form with conventional diesel. Fig. 7 highlights the desired reduction in cloud point and kinematic viscosity through addition of diesel into poultry fat based biodiesel.

Likewise, researchers (Chakraborty *et al.*, 2014; Rajak and Verma, 2018) have tested animal fats and tallow derived biodiesel in CI engine and observed a significant reduction in emission compared to petroleum-based diesel. Fig. 8(a) indicated the emission from the diesel-biodiesel (from fish oil (FO) derived biodiesel (B20)) blend resulted the lowest HC emission followed by chicken fat (CF) based biodiesel due to the higher oxygen content of the fuel. The biodiesel obtained from mixed swine and chicken fat (SCF) produced lowest NO_x emission at lowest biodiesel blend and under full load condition with comparatively lesser CO and CO₂ emission than conventional diesel. Similarly, the smoke reduction was also achieved using blended fuel at low and medium engine loads.

Besides, waste animal oils and fats derived neat biodiesel was also tested in the CI engine (Fig. 8(b)). Results were compared with diesel and it was observed that NO_x, smoke and PM emission could be diminished in case of all kinds of biodiesel except poultry fat where rise in NO_x emission was noticed.

Notably, animal waste-derived biodiesel can serve as an efficient green diesel blend for effective management of waste oils/fats disposal problem in a sustainable way while benefitting the environment with comparatively much cleaner emission.

Table 6 Properties of biodiesel obtained from different feedstocks

Biodiesel source	Flash point, °C	Cetane no	Calorific value MJ/kg	Pour point, °C	Kinematic viscosity, mm ² /s
Beef fat		57.8	38.9	12	4.637
Beef oil	156.7	60.23	39.93	12	5.3
Lard oil	143.5	57.8	36.5		4.85
Veal		52.34	39.93		6.3
Chicken fat	177	54.8	39.93	– 5	4.94
Poultry fat	172		38.5		6.86
Fish oil	155	52.4	40.54		4.45
Pork lard		74	39.5	8	3.95

Effect of emission from ethylic biodiesel of edible and non-edible vegetable oil, animal fats, waste oil and alcohol in CI engine. *Energy Conversion and Management* 166, 704–718.

Fig. 7 Effects of addition of poultry fat derived biodiesel on diesel fuel properties. Reproduced from Chakraborty, R., Gupta, A.K., Chowdhury, R., 2014. Conversion of slaughterhouse and poultry farm animal fats and wastes to biodiesel: Parametric sensitivity and fuel quality assessment. *Renewable and Sustainable Energy Reviews* 29, 120–134.

Fig. 8 Emission profile of a. Blended and b. Neat biodiesel in CI engines. Reproduced from Chakraborty, R., Gupta, A.K., Chowdhury, R., 2014. Conversion of slaughterhouse and poultry farm animal fats and wastes to biodiesel: Parametric sensitivity and fuel quality assessment. *Renewable and Sustainable Energy Reviews* 29, 120–134. Rajak, U., Verma, T.N., 2018. Effect of emission from ethylic biodiesel of edible and non-edible vegetable oil, animal fats, waste oil and alcohol in CI engine. *Energy Conversion and Management* 166, 704–718.

However, there are certain issues which need immediate resolution in order to facilitate its maximum use. The fuel property could be enhanced by reducing the viscosity of biodiesel. On the other hand, animal waste oils/fats derived biodiesel contains approximately 50%–70% unsaturated hydrocarbons which deteriorate its shelf life and make it susceptible to oxidation. Recent studies portray the application of long-chain alcohols like n-propanol and n-octanol which can improve the oxidation stability as well as depress the pour point to certain extents. Therefore, application of animal fat derived biodiesel along with long chain alcohols should be meticulously studied in order to gain perfect insight and to achieve a perfect blend that would not only have satisfactory fuel properties (meeting ASTM and EN standard) but will also nullify harmful emissions to the maximum extent.

Effect of HVO blending

HVO, a sulfur free liquid fuel, has similar chemical structure like conventional diesel. Therefore, application of HVO does not require any engine modification. The higher cetane number (79.5), lower CFPP (–35°C) and comparable viscosity (2.9 mm²/s) advocate for its suitability as a green diesel blend rendering minimal CO and THC emissions. HVO can be used in 20, 30, 50 and 100 vol% proportions. Notably, the NO_x emission for HVO blended fuel also depends on engine types; it has been found that NO_x emission is lower for vehicles equipped with selective catalytic reduction system compared to vehicles without any additional facility. Nevertheless, the exhaust emission profiles also depend on the characteristics of feedstocks used for production of HVO.

Table 7 Pyrolyzed oil (bio-oil) as diesel fuel alternative

<i>Fuel Source</i>	<i>Blends (%)</i>	<i>Engine characteristics</i>	<i>Citation</i>
Waste tires	20	1. BTE: Similar wrt diesel. 2. BSFC: 4% higher 3. HC: 14.2% lesser discharge 4. CO: 4.7% lower emission. 5. NOx: 40% more release	Sharma & Murugan (2015)
Municipal plastic	100	6. EGT: 8.3% higher temperature 1. BTE: 6% greater than diesel. 2. BSFC: 20% higher 3. HC: 3.12 times higher 4. CO: 40% more emission. 5. NOx: 42.85% lesser emission 6. Smoke: 25% more discharge	Chintala <i>et al.</i> (2018)

Effect of pyrolyzed oil blending

Plastic waste accumulated due to day-to-day activities raises a major environmental concern. Therefore, researchers attempted to tackle the issue by transforming mixed plastic waste into fuel through a thermochemical route that could be effectively used in transportation or industrial and other energy sectors. Varieties of plastics include HDPE, LDPE, PP, PET and PVC. However, since they occur in mixed form their separation techniques are cost intensive. Thus, in recent times electrostatic separation protocols were used to separate mixed plastics and served as the most cost-effective protocol. [Table 7](#) presents the performance of pyrolyzed oil either used directly or blended with diesel in CI engines.

It can be apparent from [Table 7](#) that, 100% of municipal plastic oil in CI engine renders a promising reduction in NO_x; however, other engine characteristics have deteriorated significantly. On the other hand, pyrolyzed tyre oil as 20% blend with diesel showed good performance except for higher NO_x emission. Again, the agricultural residue derived bio-oil (pyro-oil) also has a positive influence on engine performance and emission. Most common residues as feedstocks for pyrolysis include wood, coffee bean residue, mustard de-oiled cake, coconut shell, waste plant resources like mahua seeds, cotton seeds, karanja seeds, pine seeds etc., these also aids in the reduction of NO_x and HC emission.

Therefore more researches should be conducted to find out the optimum fuel blend that can advantageously affect all the fuel properties to render superior engine performance while achieving to the emission norms.

Commercialization of Green Fuel Blends

Blending of aforementioned green fuels with conventional fuel has tangible benefits on the environment owing to reduced GHG emissions and lower carbon footprint. Therefore, to commercialize the use of green fuel additives for the goodwill of mankind, the requirement of public awareness has become mandatory. With an ever increasing biofuel acceptance, the market growth of renewable green fuels is poised to increase; thereby, boosting the sales revenue and profit of the stakeholders. However, there are certain constraints that could act as a barrier in the commercialization of biofuel.

[Chen and Smith \(2017\)](#) elaborated about the hindrance faced by first-generation BE due to “food-vs-fuel” controversy along with the acceptance of second-generation cellulosic bioethanol in the U.S. This report also illustrated the three important barriers viz., biofuel production cost, competition between biofuels and petroleum fuels and policy uncertainty. The study also projected the fact that to overcome these existing barriers, additional focus would be required for further advancement in production technology along with involvement of more funding agencies for endorsing biofuel synthesis at commercial scales.

According to the EIA report, in 2017 approximately 14.39 billion gallons of BE was consumed with motor gasoline in the US; this depicts the huge market demand for BE alone ([Biofuels: Ethanol and Biodiesel, 2018](#)). Various commercial-scale bioethanol producers viz. POET-DSM Advanced Biofuels, Abengoa Bioenergy Biomass of Kansas, GranBio, Alagoas, are operational only in the U.S. which produce an average 75,000 tons of BE annually. Similarly, the Asian countries viz. Bangladesh, China, India, Indonesia, Malaysia, Myanmar and many others showed equal interests and have participated in the “Ethanol Summit of the Asia Pacific” to promote the large-scale ethanol production ([Ethanol Summit of the Asia Pacific Highlights Global Ethanol Use Opportunities, 2018](#)). Besides, Government of India also declared projects for setting up BE plants having production capacity of 1 billion liters per year ([India-proposes-new-bio-ethanol-policy-to-spur-rs-5000-crore-investments, 2017](#)). Indian Petro giants viz., Bharat Petroleum Corporation Limited (BPCL) and Hindustan Petroleum Corporation Limited (HPCL) have also signed MOUs to build commercial plants which will be operational in near future.

Likewise, global market size of BM is projected to flourish from 34 million \$ (2017) to 105 million \$ by 2022; thus, indicating a huge market demand of BM as the next-generation green fuel. Recently, BASF-SE has commercialized BM production and sales to customers in the brand name of EU-REDcert-methanol. Notably, EU-REDcert-methanol has been recognized by the European Commission under the Renewable Energy Directive (RED) as a standard to be used as a green fuel. Other multinational units e.g., BioMCN, Enerkem are pioneers in BM manufacturing where bio-methanol has been used as a building block for a range of synthetic alternative fuels.

Further, Bu being a potential green fuel blending stock, has gained equivalent attention like bioethanol and its global demand has reached 1.2 billion gallons per year. A joint venture of DuPont and BP Plc has invested in biobutanol production in large scale.

Biodiesel also occupies a major share in the renewable automotive fuel's market. The eco-friendly nature of biodiesel has increased its demand as alternative fuel in road and water transport sectors. The projected consumption of biodiesel will approximately reach 1 billion gallons only in the U.S. as per the forecasted data ([Biodiesel consumption in the United States from 2010 to 2025 \(in million gallons\), 2011](#)). At present, in the US alone, there are 124 commercial plants producing biodiesel with 2513.61 MMgy capacity. Thus, this ever growing commercialization of green fuel could eventually reduce carbon footprint through mitigation of GHG emissions from combustion of automotive fuels.

Conclusions

CI and SI engines have occupied a large market in on-road transport sectors because of high power output, durability and thermal efficiency of the fuel. Unfortunately, conventional diesel and gasoline emanate detrimental engine exhausts (greenhouse gases) which pose a potential hazard to humans causing life-threatening ailments due to enhanced carbon footprint leading to adverse global climate changes.

The present article illustrates the applications of different green fuel blends that can effectively reduce harmful engine exhausts while also improving the engine performance. Use of bio-alcohols as fuel-additives finds great attention due to its fuel efficiency and cleaner burning characteristics with extensive reduction in CO, CO₂ and HC emission. Even, bioethanol showed promising environmental and economic sustainability evaluated through LCA methodology. However, NO_x emission problem was not resolved at higher proportions of alcohol that renders benzaldehydes and formaldehyde emission causing severe damage to human health. Thus, more research should be conducted to find the optimal blending proportion along with selection of other oxygenates viz., acetone and higher alcohol (e.g., n-pentanol) for further benefits.

The inherent limitations were further attenuated by use of biodiesel derived from edible and non-edible resources including plants and animals. Animal-derived biodiesel alleviated NO_x emission to a greater extent compared to the biodiesel derived from plant resources while biodiesel derived from edible oil (e.g., soybean or sunflower oil) can completely substitute diesel in CI engines accordingly as revealed from LCA. In spite of several advantages of biodiesel as a green diesel blends for pollution reduction, still, the higher viscosity and pour point restrains its use as a neat fuel in CI engines which can be avoided by using long chain alcohols.

Again pyro-oil derived from waste plastics depicted good performance in improving exhaust emission (CO, HC and NO_x) attributes although the engine performance get deteriorated significantly with its use.

Thus, it may be concluded that blending of a specific kind of green fuel with conventional fuel may not favourably regulate all types of detrimental emissions and cannot simultaneously improve the engine performances. Accordingly, this field requires further extensive studies and experimental analyses that will facilitate in finding an optimum blend that will eventually serve as the most proficient green fuel alternative to mitigate global climate changes. Eventually, the ever rising public awareness has greatly encouraged a massive industrial production of green renewable fuels and their consequent utilizations in transport sectors which could significantly contribute in lessening carbon footprint and adverse climate changes through reduced greenhouse gas emissions.

Introduction

The term “green manufacturing” reflects the new manufacturing paradigm which supplies a variety of green policies, design and techniques to become more eco-efficient. The green strategies create products that consume minimum material and energy, alternating input materials, reducing unwanted outputs and converting outputs to inputs for creating recycling. This new paradigm “green manufacturing” is a result of market and technological drivers in the previous manufacturing paradigms. Advanced global warming, climate change awareness of the environmental risks is a result of the new green movement. The green technology with more eco-friendly product planned which helps to understand the green manufacturing aims in real practice. But nowadays, it has been seen that the interest of green manufacturing is mounting more among the research, policy makers and industrial communities a clear explanation of this term which is becoming much necessary. In this expanding urban era of the challenging world, resources and population has been found out major tribulations. The change and transform in environment through climatic change results to the imbalance of the earth. The ISO (International Organization for Standardization) has projected the new quality management system for products and environment. The main allowance is in reducing the environmental damage due to the industries. For suitable and sustainable development strategies, the new manufacturing procedure i.e., Green Manufacturing is very much necessary (Tan *et al.*, 2002). The rising demand and limited supply is the result of increasing cost of energy and resources but the trend of rising price can be projected for reaching successfully target of the companies among high price of energy and resources. While a price score may need the improvement is made to the product. On the other hand, stable prices may be assisted with mounted production efficiency, which can be achieved by diminishing resource consumption and refining the manufacturing system (Diaz-Elsayed *et al.*, 2013). Environmental issues and sustainability are very burning topics for planned business, manufacturing, product development decisions and management. In the recent year, awareness of the natural environment has return in environmentally conscious products. For lowering the environmental problem, concept of environmental management including green marketing, green organization and green production etc., are now being followed. Increasing international environmental conventions like Kyoto Protocol, Montreal Convention, Restriction of Hazardous Substances Directive(RoHS), Waste Electronics and Electrical Equipment (WEEE) and popular environmental consciousness of consumers would bring noteworthy impacts to businesses in the world (Chen *et al.*, 2006). For achieving the sustainable development, enterprises must adopt new technological process and redesign products for the problems of environmental solution (Nidumolu *et al.*, 2009). Liu *et al.* (1999) established the decision making model for green manufacturing. He examined the decision- making aim in green manufacturing, planned the decision- making objective system with five major variables. Xu *et al.* (2003) developed the green manufacturing model related meaning, mechanism, and implementation driving force.

Background

The concept of Green Manufacturing invented in Germany during the late 1980s and early 1990s. Bylinsky (1995) said that they had developed a global manufacturing standard instilling that any company willing to struggle globally must made products which can accomplish with the Green rules of European market. Programs or function regarding to sustainable manufacturing for reducing waste in production and pollution started from the 1980s. All concerned with sustainable manufacturing have been altered from process to product oriented which mainly focuses on reduction of resources, and toxic materials, energy and use of renewable materials (Seliger *et al.*, 2008). Fischer *et al.* (1997) who supported numbers of ways organizations have addressed these concerns like reducing waste, designed for recycling, and raw material consumption. In 1800s manufacturing has started from a small-scale production which developed to large scale mass production line to flexible production till 1980s. The era of customized, computerized and personalized manufacturing systems in 2000s, came into existence for mass production lines which benefited for the consumers with low cost and customized varieties of goods in mass production volumes (Jian, 2013). From the past century the demand of energy has been augmented a lot and to convert greener become a noteworthy topic in the research field for establishing more sustainable products locally and globally. Researchers, policymakers find the solutions concerning the green manufacturing in various fields have been taking places since 2011. For the solution concerning green manufacturing advised for adopting Additive Manufacturing (AM) processes including 3D printing to practice green process which reduces production steps and saves materials. The Additive Manufacturing, which is 90% energy efficient because of material loss (Ahn *et al.*, 2013). Baxter in 2001 finds out and examined the water consumption by measuring volume of daily wasted waters which regarded as one of the world's best ‘green’ strategic examples. These findings helped the company to rethink and redesign their water processing units in order to improve the wasted waters usage (Pirraglia and Saloni, 2012). Porter and Linde (1995) suggested that green manufacturing technique can be used for green industrial facilities through from workplace to improve the environmental outcomes of production processes. As per their result the green manufacturing can be adept by reducing the cost of raw material and reusing the recycled wastes, measuring the efficiency difference of production received by reducing the water usage and energy consumption and declining the environmental

impact on the public. They developed a tool as Life Cycle Inventory (LCI) for green manufacturing process which measures the compilation and quantification of the raw materials (inputs) and their emissions (outputs) for test production material throughout its life cycle. [Lele \(2009\)](#) analyzed the need for meeting individualistic customer demands brought about the introduction of flexible and mass customization techniques. Environmental protection laws, regulations and tax implications are already in put in many countries ([Gungor and Gupta, 1999](#)). While environmental regulations and public pressure, coupled with economic and technological factors have prejudiced industry worldwide to become more environmentally conscious and Green urged ([Shrivastava, 2003](#)). Green Manufacturing is gathering the needs of the present generation without giving concession to the ability of future generations to meet their own needs ([Mendler et al., 2005](#)). Green Manufacturing decreased to waste and pollution which measured the reduction of natural resources ([Cortellini, 2001](#)).

[Florida et al. \(2000\)](#) demonstrated the Green packing, distribution and EOL use into GM. [Atlas and Florida \(1998\)](#) examined that Green Manufacturing involves efficient production processes including source reduction, Green Design and recycling. [Gutowski \(2002\)](#) demand manufacturer's consideration for the environmental impact at all stages of the production process through resource saving, and components recycling. [Zhang et al. \(1997\)](#) analyses that Green Manufacturing technologies and design practices will permit manufacturers to turn waste into a gainful product. [Chien and Shih \(2007\)](#) Green Manufacturing technology through sustainable design of products and processes save energy and diminishes dependence on non-replaceable raw materials. Green Manufacturing is more than using Green resources which is based on manufacturing for reuse ([Bylinsky, 1995](#); [Norberg-Bohm, 1999](#)).

Importance of Green Manufacturing

The Green Manufacturing plant ends to reduce the Greenhouse gases produced by human activities on the environment which can range from complex industrial production processes ([Thurner and Roud, 2016](#)), associate with global warming, sustainability of cities, air contamination, waste, pollution, scarcity of energy sources and population growth. The greenhouse effect which caused by engorged greenhouse gas emissions including Carbon-di-oxide, Methane, Nitrous oxide and Fluorinated gases which originate trap heat in the Earth's atmosphere. Human actions like deforestation and burning of fossil fuels have provoked the greenhouse effect, resulting global warming which is affecting the environment in different ways like desertification, increased melting of snow and ice, sea level rise and stronger storms and extreme events, other effects are contain ocean acidification, variation in plant growth and nutrition levels, smog and ozone pollution and ozone layer depletion. Hence, we can infer that Green means ecological sustainability. Green innovation has also turned into one of the crucial strategic parameters to obtain sustainable developments in manufacturing industries caused by the escalating environmental pressure. In present day, strict environmental regulations and famous environmentalist have changed the competitive laws, rules and patterns for companies, whereas in previous, spending in environmental activities was considered as needless.

[Zhang et al. \(1997\)](#) has explained that if products lifecycle shift from the drawing board into the production line while the environmental attributes of it are basically fixed. Thus for estimation of the environmental consequences in each sector, support the design function with tools and methodologies is very necessary. [Liu et al. \(2005\)](#) advocated that Sustainable development is a key approach which environmental control and resource usage can be done, despite continuous expansion. Green technology is much needed for understanding the causal relationship between Green Manufacturing and corporate environmental performance. Rising industrial activities led to the global problem of unfavorable environmental impact. In order to get rid of it from the very source, Green Manufacturing. Life cycle analysis (LCA) are now being pursued urges [Rivera-Becerra and Lin \(1999\)](#). Thus Green Manufacturing is the only obvious solution for today's manufacturing scenario while many manufacturers consider environmental management as an integral part of economic development and a need for residual competitive in business ([Sawhney et al., 2007](#)). [Allen et al. \(2002\)](#) find out many relevant and related program of action and boost many aspects for the problem like waste, emission, energy usage, Greenhouse gases, and product recycling. [Seliger et al. \(2008\)](#) demonstrated that use of Green Manufacturing, proper use of resources and Green treatment are currently very significant issues for governments and industries worldwide. The scientific approaches have also been focused on the material level recycling. [Tseng et al. \(2006\)](#) advocated that minimizing wastes and emissions at source can improve the environmental and economic performance of an organization. Thus, it can be concluded that Green Manufacturing is an importance issue and it needs to be explored in detail at world level.

Transformation to Green Manufacturing

Green Manufacturing is an idea or a process which is a method for manufacturing that control pollution and reduces waste by proper design and process of product. It is the mandatory and responsibility of individual to conserve the resources for future generation which is main objective green manufacturing. They should also be aware related environmental sustainability and ascertain the acceptable level of toxic emission to the environment. Green manufacturing creates a status for public's savings on useless cost and promotes research and design where the process of green manufacturing involves investing in production process development rather than control technology, substitute renewable sources for finite ones, product recycling, and the companies must decide whether to make or buy the product. The mounting global environmental change and other features of environmental misconduct have given go up to concerns about economic enlargement more than the Earth's carrying capacity. Government's environmental aims should be accomplished in parallel with positive economic development; a transformation of the industry is needed. Most of the international organizations and developed countries have proposed various ideas and initiatives such as green economy, green growth, green transformation, sustainable transformation and green industrial strategy ([Luitkenhorst et al., 2014](#);

OECD, 2013; UNEP, 2011; World Bank, 2012). Green structural transformation means to change in the national economy in which carbon intensive industrial sectors minimized their share of the gross domestic product (GDP). Green transformation refers to processes within industries which lead to minimized environmental change impact (Growth Analysis, 2014).

There are three areas for the Manufacturing Companies to be focused including green energy, green products and green process.

Green Energy which created energy by natural sources including rain, tides, algae, sunlight, wind and plants and recycled it. Fossil fuels are a specific reserve which have been developed before millions of years and will continue to reducing with use. There are five energy sources like Municipal solid waste, Biomass- wood and wood waste, Landfill gas and biogas.

Green Products means “sustainable” which refer to products and service that utilized for economic betterment for sustainable development. Green products is characterized by Energy efficient and precaution for Ozone depleting chemicals, toxic compounds and nontoxic byproducts, plan for using recycled materials/content or from renewable and sustainable sources, acquired from local manufacturers or resources and easily reused either in part or as a whole.

Green Processes in business Operations: A green environment is a burning issue among social and business aspects. A large part of the global community is grateful to make actions toward an environmentally sustainable operation which reflects their social responsibility. This reengineering of business processes is characterized by areas of green which containing to efficient, effective, agile, necessary and measurable with life cycles. Therefore, framework includes five aspects focused on business processes with green process characteristics, merging business processes with the environmental standards, green business process redesign, training programs development and change management, performance monitoring and process improvement (Lan, 2013).

Environmental impact of all stages of production is essential for considering green manufacturing. The manufacturer should avoid from using any materials which are harmful to the ecosystem in the design, production, field application and end of life disposal stages of the product. Green manufacturing is also the expression of the sustainable development policy and the cycle economy mode in modern manufacturing. The following sphere are needed for green manufacturing including Recycling, Bio-degradable Materials, Alternative Energy (Wind, Solar), Waste-to-Resource (Biomass Pellet Fuel), Product and Packaging Design and Energy Efficiency (LEED and Automatic Doors). Implementation of green manufacturing needed the following principles: which contains eco-friendly materials and energy, prevent waste, specific separation and purification process, optimized utilization of mass, energy, space and time efficiency, design for durability not immortality, Minimization of material diversity, Utilization of local materials and energy flows, Using renewable resources (Pirraglia and Saloni, 2012)

Hence forces driving Green Manufacturing are related with five factors:

- (1) Increasing energy and input costs.
- (2) Awareness to consumer for Green products of the company.
- (3) Forcing regulatory environmental and waste management laws for the companies and pressurized to policy makers for following the same.
- (4) The companies must make technological advances for new business benefit.
- (5) Requirement for enhancing competitive differentiation between companies, particularly for first movers or those who are able to break the compromise between short-term higher costs and numerous benefits (example: brand premium, new customer segments) (Turner and Roud, 2016).

Green Manufacturing in Developing Nations With Special Reference to India

It has been seen that after the World War-II, industrial advancement has given a new dimension in the process of urbanization in developing countries, which also resulted in the human development. It is recorded that only 160 million people (one tenth of the then population) were living in the urban areas in 1900 but almost 3.2 billion people are expected to inhabit the urban areas in 2016. Most of this projected growth will be increased in the developing countries due to economic affluence, better social and civic amenities, degradation of rural areas and population increase. The industrialization has totally changed to the human settlement pattern and livelihood. It has been accounted that most of the jobs were in the agriculture fields only, confining the population to rural areas during the period up to about 1950, but now most of the jobs are in service sector which as a result of industrialization, pushed the people towards urban centers. Cities occupied about 2% of the world's available surface area. About 78% of carbon emissions estimated from fossil fuel combustion and cement manufacturing while 76% of industrial wood use occur in urban areas. It has been recorded that 60% of the total water tapped in the world for human consumption which consumed by the cities. It is also found that almost half of this water is used for irrigating the food crops consumed by city dwellers, roughly a third used for city industries and the rest used to meet the requirement of sanitation and drinking water (O'Meara, 1999).

The most serious problems facing the world today are: scarcity of water and food supply, extreme instability in energy and food prices, augmenting greenhouse gas emissions, severe income difference, chronic fiscal imbalances and terrorism (World Economic Forum, 2012) either from environmental mismanagement or dissimilarity, or both. Aside from the chronic economic imbalances that mostly concern the developed economies while developing countries are the most susceptible to all of these risks. The key question is if environmental aim can be resigned with growth and poverty reduction in the developing world. This report states that these objectives can indeed be pursued simultaneously in a mutually reinforcing way through green and inclusive enlargement. Advanced countries boards on huge industrialization through manufacturing for more benefits. Developing countries are also taking on similar plan to make the most of their natural resources. Nations have begun improvement their manufacturing methods through the adoption of eco-friendly processes. All over the world manufacturing companies have resorted to save

environment enterprise and marketing activities due to the expansion in the environmental complexity and mounting public demand to reflect on the effects of their activities in the environment (Kotler, 2011). In manufacturing industries, strategic approaches have been accepted by several firms to meet the concerns of stakeholders while producing goods that meet customer expectation related environmental safety (Hult, 2011). Customer expectations is the alteration in current products while bringing on board new products and processes objective for reducing environmental effect, but instead get better the environmental protection by firms (Cronin *et al.*, 2011). Studies have been conducted under various titles by academicians to find out the motives and processes adopted by firms to innovate in their product lines. Among these titles include green product innovation (Dangelico *et al.*, 2017), environmentally conscious product strategies (Pujari and Wright, 1996; Katsikeas *et al.*, 2016), eco-design practices (Sarkis *et al.*, 2010; Yu *et al.*, 2017), green product development (Chen, 2001; Johansson and Sundin, 2014) and environmental new product development (Pujari *et al.*, 2003; Jabbour *et al.*, 2015).

It is regarded that natural ecosystem and manufacturing have always been associated in some method. Enhancing output of manufacturing firms is the capacity to augment market sector for these products with making high profits on manufacturing. The ability of some on the other hand few firms ability like in those agro-industry to effect taken demand the operations of other manufacturers is likely to create sideway linkages, which originate from one firm making use of the by production waste taken out from initial production processes according to the Food and Agriculture Organization (FAO, 1997; Al-hassan *et al.*, 2013). FAO (1997) demonstrated that how manufacturing firms such as those in the agro processing sector add to the general enlargement of economies throughout the world. In spite of these advantages, the manufacturing sector also has pessimistic environmental impact including release of toxic waste into water bodies, and the release of toxic gasses into the air, thus affecting the clean air. Though these challenges exist, several nations lack the vision, plans and structures that are capable of overcoming these ecological challenges.

The rapid economic and industrial growth of India result to urbanization has come at the high cost of increasing Green Hough Gases emissions, growing demand for scarce resources such as mounting waste generation from urban centers. Today, India is the fourth largest economy in Purchasing Power Parity terms and the fifth largest Greenhouse Gases emitter in the world. In India, CO₂ emissions augmented more than 150% after China during 1990–2008. As per Confederation of Indian Industry (CII) and the Boston Consulting Group (BCG) report, India produced close to 4 million tons of hazardous waste from industrial and bio-medical sources which cause water and land pollution, while on the other hand e-waste is also becoming a major area of concern for India. Estimates suggest that only 3% of e-waste makes it to endorsed recycling facilities, with the rest either going into landfills or being processed at informal recycling yards. The said report advised that to overcome these challenges or at the very least to reduced their impact, the Indian manufacturing sector will need to take concerted action on all three areas containing Green energy, Green products and Green processes in business operations.

In Asia India is a third largest economy in Growth Domestic Production and as the one of the fastest growing economies in the world. In India, the gross national income was 105.27 trillion with an annual growth rate of 7.4% during the period of for 2014–15 (Economic Survey, 2014–15). It has been reported that services sector was the largest share in total GDP of India i.e., 57% (2013), followed by industrial sector 25%, and agriculture sector 18% (World Bank Development Indicators, 2015). Total population of India has been counted as 1.29 billion and its share was around 17.84% in the world population. At the global level in 2014 the economic growth has been noticed picked up in the last one year and it has been expected to further increase during 2015–16.

Table 1 shows the distribution of development in India and select countries. The economy in India should be develop for its achievement and further advancement but for developing countries like India, environmental consequences can be significant as it will place serious restraints on natural resources like land, water, minerals, and fossil fuels, driving up energy and commodity

Table 1 Distribution of development in India and selected countries

Country	GDP in billion (constant 2005 US\$) ^a	GDP per capita (constant 2005 US\$) ^a	CO ₂ emissions (MT) ^a	CO ₂ emissions (metric tons per capita) ^a	Energy use (kilograms of oil equivalent per capita) ^a	International Trade Balance in Goods ^a	Cash surplus/ deficit (% of GDP) ^a

prices. The extent to which its economy “grow green” will depend on its ability for carrying economic growth which leads to enhancement of social equity and job creation. Green growth could play an important role in balancing this priority. However, managing economic shortage and public debts are two key challenges for national policy making, which could make technological change required for green growth more complicated. Hence, it becomes essential to understand and maximize the development benefits, such as income, energy access, and trade, of green growth involvement across all sectors.

As per Central Pollution Control Board, recorded that class I cities and class II towns in the country produced around 38,254 million liters per day (MLD) of sewage which only 11,787 MLD (31%) is treated and balance is discharged untreated. Forest Survey of India, 78.92 million hectares covered by forest and tree cover spreads across and represents 24.01% of the geographical area of the country. It has been accounted that rise in forest covered area by 5871 sq. km compared to 2011 assessment but there has been slight decline in moderately dense, and mount in open forest category. The decline in mounting stock of the country as 389 cu. m has been noticed during 2011–2013, which suggests a reduced in quality of forest in spite of the increase in forest and tree cover.

India has only 2.4% of the world's land area and harbors a significant proportion of recorded species. Of the 34 global biodiversity hotspots, four are present in India that including the Himalayas, the Western Ghats, the Northeast, and the Andaman and Nicobar Islands. International Union for Conservation of Nature Red List, 1039 species was categorized as threatened species for India in 2015. The National Institute of Hydrology estimates India is affecting towards perennial water shortage and found out that water availability in India to be 938 cubic meters per capita per year, which with less than 1700 cubic meters per capita per year is considered as water stressed. Additional water demand will increased from the domestic and industrial sectors where is an urgent need for water efficiency measures in all sectors, especially in irrigation, which is projected to be so even in 2025 and 2050. It has been found out from past studies and observations that the annual mean temperature of India has showed noteworthy warming trend of 0.51°C per 100 year, during the period 1901–2007 with augmented warming during 1971–2007 (Kothawale *et al.*, 2010). Warming trend in the Indian sub-continent and the ecological impacts expected with even 2°C of warming are quite intense in it where the situation could be much worse due to higher temperature rise as per projection of 2030. Energy supply in India is heavily dependent on fossil fuels with petroleum products and coal which accounting about 88% of the total primary energy supply. In 2012 as per International Energy Agency, India had more than 300 million people who were deprived of electricity and more than 800 million people were dependent on solid biomass as fuel for cooking. As per census of 2011, 43% of rural households used kerosene as primary energy source for lighting. Since energy access has strong growth implication, this is a serious challenge that the government is currently trying to address. Cities contribute to almost 2/3 of India's GDP (MOUD, 2015) and will assume even greater role as India embarks on higher economic growth. Indian cities faced severe challenges associated to quality and availability of infrastructure, such as power, telecom, roads, water supply, and mass transportation, which could pose serious constraints to economic growth if left unaddressed. It has been seen that the Government of India would like the manufacturing sector to play a bigger role in the economy of country. The Ministry of Commerce and Industry, Government of India has set a target to increase the sector's contribution to the Growth Domestic Production to 25%, from the current level of about 16% for growth strategy in green manufacture. The said growth is very much necessary for the country's environmental concerns need to be mitigated the manufacturing sector must use energy and resources efficiently for minimizing generations of waste. It is found out that even if every factory, power plant, car and airplane is shut down, the average global temperature would still increase by 0.6°C in this century. Green manufacturing engaged transformation of industrial operations in three ways: (1) Using Green energy, (2) developing and selling Green products and (3) employing Green processes in business operations. 92% of the companies surveyed are engaged in Green initiatives recorded as per a recent global survey by BCG.

There are disparities regarding for adopting Green across the sectors. Few sectors take it up due to regulatory compulsions (power), while others see it as an opportunity to build a stronger brand with consumers (retail). Steel manufacturers have adopted Green projected to stabilize mounting energy costs on the other hand automobile companies launch electric and hybrid cars to meet increasingly stringent emission regulations. The impact of Green initiatives also varies by the industry sector like green initiatives in the power sector have the greatest impact on reducing CO₂ emissions followed by transportation and then the industrial sector. Green manufacturing in India has been significant policy development and adoption by the manufacturing industry in the area of Green energy, there is substantial scope on both the policy front and its adoption in the areas of Green products and Green processes. Successful transformation into Green manufacturing will bring fabulous advantages for the nation development.

Green Manufacturing and Industry Perspective

Green as an Integral Part of Business leading Sustainable Development: At the same time, businesses can find approaches that will move towards social wellbeing, environmental protection and economic development. Sustainable development leads to adopt business strategies and activities to meet the requirement of the enterprise and its stakeholders today, while protecting, sustaining and enhancing the human and natural resources (Yang, 2017). But it has become a cliché that environmental problems are substantial, and that economic growth contributes to them. The common approach is stricter environmental regulation, which generally constrains expansion. Sustainable development in good business opens new ways for supplier as green consumers, environmentally safer materials and processes that invest in eco-efficiency and those that lead themselves in social well-being. Environmental challenges are forcing to alter the regulatory and market landscape of businesses tending towards green business and energy-efficient companies will be better able to navigate these regulatory changes and be better positioned to climate negative events like energy price spikes.

Also, nowadays end users like to buy safe, non-toxic, green products. Consumers are becoming more educated about their choices and are willing to invest more in a green product to participate in environment movement and to protect their family.

Recently, many of the world's leading organizations are investing billions of dollars into environmental sustainability programs which is a good indication that small business owners should follow these with following steps: Making green thinking a part of company culture, Swapping to LED Lighting, Eliminate plastic, Doing business with green vendors, Organizing a fund-raising event and Recycle and reuse.

Green Manufacturing in Traditional Industries

Nowadays relating with environmental movement, generally the relative impact and performance considering green energy vary significantly, depending on the intensity of energy and carbon footprint of the industry segment. Considering the emission of greenhouse gas, power generation is the highest emitter, followed by transportation and manufacturing. So, green initiating influencing the three sectors.

- (1) *Power generation*: Globally in 2008 average 20,000 TWH of electricity has been used, it is expecting this amount will be increased approximately 2.8% per year and in 2020 it will reach 28,000 TWH ([International Energy Agency, 2012](#)). Fossil sources such as coal, oil and gas produce three quarters of the current electricity which poses several challenges for human being.

(A) It is projected by 2020 that increasing global warming with greenhouse gas emission levels already exceeding 380 parts per million (ppm) and expected to reach 400–430 ppm (Inter-governmental Panel on Climate Change (IPCC)). (B) Energy prices are expected to rise, with scarcity of fossil sources, and creates global economic crisis. (C) The political instability in resource-rich countries has the industrialized nations worried about energy security ([Bhattacharya et al., 2011](#)).

In present days power-generation industries are adopting many green energy technologies which are becoming competitive with fossil fuels while others are still expensive (BCG report on potential of solar power generation: "Solar Storm", BCG report on alternate energy: "What's Next for Alternate Energy?"). The power sector need to develop a detailed understanding of the cost and development trajectories for renewable (Water, Biomass, Solar etc.) and include them in their fuel portfolios.

- (2) *Transportation*: It is another 'non-Green' industry problem for which governments around the world are aware. Due to strict Government policies, concerns of energy security and higher oil prices, and equally demand of enhanced public approval of Green brands, virtually all leading automobile manufacturing companies are in the path to control the CO₂ emissions of their vehicles and making it fuel efficient. Thus, the new clean propulsion technologies are adopted by the automotive industry containing power trains, electric cars and fuel cells. If the industry starts to control on the cost-benefit trade-offs in creating and owning a Green car and offering consumers an attractive value proposition, the share of these products could well reach close to 50% by 2020 (BCG report on increasing the potential of Green vehicle technology: "The Comeback of Electric Car?") ([Bhattacharya et al., 2011](#)).
- (3) *Manufacturing*: This sector also needs Green Initiative. Based mainly on fossil fuels, Steel is an energy-and-emissions-intensive manufacturing industry. The iron and steel industries account for close to 20% of all energy consumed by industries worldwide and about 30% of the world's direct industrial CO₂ (Greenhouse Gas) emissions, as per International Energy Agency (BCG report on sustainable steel manufacturing: "Sustainable Steelmaking") ([Bhattacharya et al., 2011](#)). Industry- caused CO₂ emissions aggregate about 25% of the total worldwide emissions with following:

Iron and Steel Industry 30%, Non-metallic minerals (e.g., Cement) 27%, Chemicals and Petrochemicals 16%, As per energy consumption 14%, Chemicals and Petrochemicals 28%, Iron and Steel Industry 20% and non-metallic minerals production 10%. Thus, for reducing Greenhouse gas emissions at the global level, improving energy efficiency of the manufacturing sector is very crucial. Policy makers are tightening controls and charging fines on GHG emissions and waste disposal and also nowadays financiers prefer companies maintaining environmental sustainability. Increasing energy prices also have influenced the competitive positioning of many industry. In case of rising fuel prices coupled with tightening environmental regulations and the challenge of maintaining competitiveness, must be forced that steelmakers should change their working conditions by both minimizing their energy intensity, and controlling environmental pollution. Energy-demanding industries always cost low levels of R&D spending rather than other industries such as semiconductors and pharmaceuticals. In spite of this challenge, quiet developments in energy efficiency continue to proceed within these industries. GHG emissions from the industries can be reduced with following three main ways: Enhancements in efficiency that can be applied through the recycling of waste materials and changes in the product design, Replacement of feedback, for e.g., Greater use of biomass and GHG capture and storage such as CCS. For sustainable energy consumption there are two main pillars:

- Energy efficiency
- Renewable energy use

These two pillars are deeply rooted in the foundations of energy policy in case of manufacturing and production. A multidisciplinary challenge combining science, ecology, information technology, technology and common sense, is achieving energy efficiency.

Emerging Technologies for Green Manufacturing

For making the traditional businesses Greener, and creating new business setup, emerging new technologies must be needed. Generally, there are five broad categories of technologies for reducing GHG:

Carbon sinks: With this developing technology, Carbon Capture and Storage (CCS) are made for using in power plants which are fired by fossil fuels such as coal. This technology enables capturing and storing CO₂ from fossil fuels, being trapped and stored in underground wells under severe pressure as liquefied form. Thus, it does not pollute the atmosphere. Efficient fuels: Using cleaner fuels such as hydro power, biomass, Integrated Gas Combined Cycle (IGCC), etc., for generating power also need some technology. Consumer Green: At the user end have to use clean and efficient fuels, for example, off-grid solar power applications like solar water heating and building insulation and solutions. Green transportation: Pollution less fuel cells, electric vehicles, and bio-diesel may use for green transportation. Industry efficiency: In traditional industries such as iron and steel, cement, refining, chemicals, etc., have to use green production methods and technologies (Jian, 2013).

Categorizing technologies based on two dimensions (maturity and availability), provides guidance in making business model choices. For example, based on relative technological and commercial maturity some technologies such as biomass, hydro and off-grid solar score higher, whereas other technologies like tidal waves, wind offshore and concentrated solar power are relatively nascent. Again, some are globally available technologies (IGCC and CCS), others (geo-thermal and waste to energy) are available in selected geographical places. Solar energy is generally cost effective, and in the areas of water and waste management many mature as well as emerging Green technologies are available.

Green Manufacturing From the Perspective of Green Information Technology

Today weather change, environment and climate change very big problems, there is no easy solution to minimize and control it, which is a big challenge in front of business world and it is impossible to ignore the ongoing awareness related same. Thus, the IT community have a significant role on the worldwide carbon footprint by adopting a 'greener' approach to computing. Green Information Technology is a collection of strategic which minimize to the carbon footprint of an organization's computing operation. Green Information Technology is not only practiced on minimizing the impact of the ICT industry but also using the services of ICT for reducing the organization's overall carbon footprint. The Green Computing, as defined in the Official Journal of the French Republic on July 12, 2009, the ESTs of information and communication for short eco-ICT, are information technology and communication which design or use can decrease the negative effects of human bustle on the environment. About 60%–70% energy is consumed by computers which are not in use but still turned on and that consumed energy is the main reason of CO₂ emission (Mittal and Kaur, 2013). Considering Jevons's paradox technological progress that increases the efficiency with which a resource is used tends to increase (rather than decrease) the rate of consumption of that resource. This paradox is well supported by Moore's law, 2005 which predicts exponential growth in the power density, and total power used for IT. On the contrary there is linear growth in power generation mechanisms (Harbla et al., 2013). The Grid Computing as a rising technology is a pivotal instrument that bridges the gap between being remote and industrialized. One of the prime movers in the technology that we have these days is the use of the grid computing. This technology allows for the distribution of the PC effectiveness where there is an extraordinary computing device with resources comparable to a super computer that acts as a "server" for a group of computers that then act as work stations which methodically work as a group in order to achieve a common goal.

In case of Green IT (green information technology) which is environmentally sustainable computing, procedure is to minimize the negative impact of IT operations on the environment by designing, manufacturing, operating and disposing of computers and computer-related products in an environmentally-friendly manner. It reduces the use of hazardous materials, maximizing energy efficiency during the product's lifetime and promoting the biodegradability of unused and outdated products. Green IT is also used technologies for redesigning of data centers and the growing popularity of virtualization, green networking and cloud computing (Xiang et al., 2016). Being Green means different things to different peoples. For some, it might mean buying technology that's more energy efficient than what they have & reducing the amount of electricity a data centers consumes. For others, it means buying hardware that is made of environmental friendly components. Yet others might seem at the end of hardware life and suggest that Green IT means proper disposal. The global green mantra is 3 R's that is "Reduce, Reuse, and Recycle" (Velte et al., 2008).

Technologies Green Computing: A VIA Technologies Taiwanese company which manufactures motherboard chipsets, CPUs and other computer hardware, that introduced its initiative for "green computing" in 2001. With this green vision, the company has been showing on power effectiveness throughout the design and manufacturing process of its products. Carbon-free computing: According to one of the VIA Technologies' ideas, is indicating to decrease the "carbon footprint" of users – the amount of greenhouse gases produced, measured in units of carbon dioxide (CO₂). Greenhouse gases are responsible for earth's more or less stable temperature as because it naturally blankets the Earth. For increasing the concentration of the main greenhouse gases – carbon dioxide, methane, nitrous oxide, and fluorocarbons – Earth's temperature is increased, which could lead to severe floods and droughts, rising sea levels, and other environmental effects, affecting both life, society and the world's economy.

Solar Computing: For solar computing, VIA partnered with Motech Industries, one of the largest producers of solar cells worldwide. As sun is rich source of alternative energy, amid the international race toward alternative-energy sources, VIA is setting its eyes on the sun, and the company's Solar Computing initiative plays an important role for its green-computing projects. Lead-Free and RoHS computing: No requirement of a lead bead, VIA's lead-free manufacturing technologies and the solder balls now consist of a tin, silver, and copper composite. Energy-efficient computing: The development of energy-efficient platforms for low-power, small-form-factor (SFF) computing devices (Jindal and Gupta, 2012) is a central goal of VIA's green-computing initiative.

Green Principles: Eco-Friendly Approach: It was realized that the conventional computers take much energy and produce heat. The main aim of the manufacturer is to decrease the e-waste in the environment. In these computers, hazardous material such as PVC's

Fig. 1 Green manufacturing focus.

Fig. 2 Domains of Green IT. Reproduced from Murugesan, S., 2008. Harnessing Green IT: Principles and practices. IEEE IT Professional, 24–33.

brominated flame-retardants and heavy metals such as Cadmium, Mercury and Lead are not used like commonly used computers (Masood Anwar, 2013). The Green IT principles show the concepts of reducing the environmental impact. The Fig. 1 focused on different areas and activities. It presents the four green holistic principles. These principles are focused on different sectors and activities as follows: Green use – Decrease the energy consumption of data centers, computers and other information systems by using them in the environmental ways e.g., virtualization, turning off computer when not in use, etc., Green design – Energy efficient and environmentally sound components, computers, servers and equipment's have to be designed and also concern more on the future of electronic parts e.g., eco-friendly design, LED monitor, etc., Green manufacturing – A low or no impact on the environment should make an important factor in every process in manufacturing electronic components, computers and other associate subsystems. Green disposal –The plan should be made by company for refurbishment and reuse of old computers. Also, rules of recycling process for unwanted computers or other electronics components should be prepared (Fig. 2).

Benefits of environmental protection and cost reduction: Murugesan (2008) has identified the three drivers of Green IT as economical, regulatory and ethical. Bose and Luo (2011) also demonstrates that “the three primary drivers of Green IT” initiatives according to the literature including reducing costs due to budget cuts, decreasing consumption due to resource restrictions, and complying with the local law. Therefore, it is evident that Green IT aims at cost reduction as well as environmental protection (Tushi et al., 2015). Green IT Personalities, through discussion with IT and business decision-makers, four predominant Green IT Personalities emerge. The Green IT Personality Matrix plots Green Attitudes & Action on the vertical axis and implemented Green IT initiatives on the horizontal. The four personalities are Green Advocates, Smart Spenders, Green Seekers and Green Observers as Fig. 3 depicts this.

Green Awareness, Green Consumption: There are two major factors of consumer green awareness and green purchasing behavior: (1). Consumer's environmental concern, and (2). products functional attributes. Environmentally responsible purchasing is important for day to day life. People are changing their trends and way of lifestyle in a more conscious way paying more attention towards green consumption, relating with the environmental significance of purchasing, using, and disposing of various products, or adopting various green services. The social values of consumers are directly co-related with consumer's awareness of green products. Companies are used to adopt green advertisement strategies for creating positive green brand awareness. Relating with green awareness, green marketing also changes a wide range of activities such as modification of product, production process, packaging changes, as well as modifying advertising etc., for making business success and fulfill consumer's need.

Barriers to consumer's higher green consumption: For motivating consumers towards adopting sustainable green consumption, only a basic understanding of ecological and social problems might not be enough. For environment protection and a deeper thinking of the consequences of irresponsible consumption should play more effective role in making the consumer shift towards green consumption.

Fig. 3 IBM and Info-Tech Research Group, 2016.

Barriers to Consumer's higher Green consumption are related with some factors like Individual factors, Emotions, Habit, Recognized consumer effectiveness, Observed behavioral control, Values and personal norms, Trust, Knowledge, Situational factors, Price, Product availability, Product attributes and quality, Brand image and Eco labeling and certification etc.

Framework for adopting green manufacturing: Advantages and disadvantages of Green Manufacturing: At the time of converting the business into a green or environmental friendly, manufacturer, it obviously, decides to maintain certain values aiming towards the goal of protecting the environment as well as focusing on things viz technological innovation and progress. Serving to the Environment which can be directly protected by green manufacturing through reducing waste and harmful emissions and work toward protecting resources that are finite and nonrenewable. By green manufacturing, a business can also gain new customers as many customers want to support businesses which implement green manufacturing.

Improving the business: A company should improve its public relations by implementing green manufacturing as the end users are feeling the need of protecting the environment. As a result, it can lower costs for the business over the long term through the implementation of more efficient systems and fostering a company culture dedicated to innovation in processes. Also, these more efficient processes must result in lowering the amount of waste a business produces.

Remaining the transition: A business can experience relates to the transition to green manufacturing which is disadvantages of green manufacturing. Manufacturer has to continuously look for funding sources to finance for converting to green manufacturing. In a nutshell implementing green manufacturing can cost business significant amounts of money, although the process may save the business money at end. Over and above, this new movement requires not only the implementation of new manufacturing processes, but also the ability to design and build the necessary technology and machinery to support green manufacturing. Also, a business will discover new talent to come in and educate current employees on how to work in the new green manufacturing environment (Rusinko, 2007).

Disadvantages relating international trade: For going green, another important disadvantage relates to international trade. Many businesses stumble to implement a green manufacturing system because they scared about that this process will become a burden to the free flow of goods and profitable trade deals. This restriction can apply to a wide range of manufactured products and industries. For example, a business might restrict to start green manufacturing in anticipation of losing an international supplier who does not participate in green manufacturing.

Economic assessment and making strategic choices: An economic assessment requires estimating the 'value' generated over the long term through the green initiatives in case of adopting green manufacturing. It should maintain all parameters of value creation – from quantitative metrics like pricing power and cost savings, to qualitative ones like employee recruitment and engagement. Companies will get long term benefits of Green by following these. For an optimistic solution, companies have to be very clear vision about their strategic choice on how green manufacturing they want to be, and why. The potential impact (Bhattacharya et al., 2011) of sustainability efforts containing powerful brand and greater pricing power, Better operational efficiencies, More effective use of resources, Optimization of supply chain, Reduced costs and taxes, Increased ability to attract, retain, and motivate employees, Higher employee productivity, Enhanced customer loyalty, Improved ability to enter new markets, Promising sources of revenue, Operational risks, lower market, balance-sheet, Decreased cost of capital and Better access to capital, financing, and insurance.

Implementation Framework for Green Manufacturing

Plan, Execute, Communicate: There are approaches (Rusinko, 2007) to environmental practices: Pollution Control, Pollution Prevention and Product Stewardship. Pollution control, "end of pipe" approach, refers to the methods to trap, store, treat, and/or dispose of pollution. It is viewed as costly and non-productive as it represents an expense that yields no potential for competitive advantage. Pollution prevention reduces or prevents pollution and can result in lower costs, reducing the usage of resources, reducing

the amount of waste generated and recycling. So, resource productivity and competitiveness can be improved by product and process innovations which reduce or prevent pollution. Generally, pollution prevention is defined here as mainly manufacturing and operation oriented, Product Stewardship boosts the environmental outlook to the whole value chain and includes other internal and external stakeholders such as R&D, product designers and suppliers. It includes reconstructing products and processes to be more environment companionable, by using renewable resources and reassuring suppliers to practice pollution avoidance and product stewardship. Product Stewardship may grant the companies to gain competitive benefit through competitive preemption. With this, green manufacturer's reputation may attract new customers, and manufacturing quality will be enhanced. Thus pollution prevention and product stewardship can be specified to as environmentally sustainable manufacturing practices. There are some methodological limitations are found as competitive outcomes of empirical research on environmental manufacturing practices.

There are three-step implementation framework has to be maintained. *Plan*–Companies require to plan broadly to increase the use of Green energy, shift the product portfolio to Green products and business operations towards Green processes and future gain or loss. These are related to long term business. Green targets and metrics must be related with a sustainability charter, based on short term and long-term goals. Companies should develop Green indices or scorecards specifying the significance of the Green initiatives they have maintained. With this company's should agree for specific targets on those indices and point out progress against those targets (Eunsung and Sung-Yong, 2016). *Execute* – With green energy, green product, and green processes in business operation, a robust plan must be opted and targets clearly defined and monitored.

Conclusion

Generally, information about production, work planning and real-time information in manufacturing is actively related with energy management. For this, infrastructure for related information sharing, integrated monitoring, planning, control and analysis are necessary. So, integration of the energy management system with the information network is the requirement of Green Manufacturing system. Also, manufacturers would become not only consumers, but also suppliers by using their own energy resources. Prevention of environmental pollution, using renewable energy, applying legal regulations and fulfillment of stakeholders and customers' requirements are necessary tools to improve the performance of Green Manufacturing. Generally large manufacturing industries have capacity can heavily invest on the green awareness than small manufacturing capacity industry because larger industry invest much on green concept. In a nutshell, green manufacturing is more than a social issue. The benefits of adopting this technique and concerned costs are easily justified relating the benefits of adoption.

Implementation of Green Manufacturing technologies is not just a social compulsion but a growth catalyst. Adoption to green manufacturing has the possible to achieve sustainable development and eliminate poverty. So the leaders, society and leading businesses should be collaboratively engage in this conversion which will require a continued attempt on the part of policy makers and their constituents to re think and redefine traditional measures of wealth prosperity and wellbeing. It has been find out that a green manufacturing economy substitutes clean energy and low carbon technologies for fossil fuels, which addresses climate change, creates jobs and decrease import dependencies. However there are many perils and challenges along the way for the industries and for the government therefore taking these risks and facing these challenges would certainly assist any country to become a green economy with mounted manufacturing would also help in bringing about sustainable development.

Green Mining of Rare Earth Elements (REE) to Diminish Greenhouse Gas (GHG) Footprint

Ratna Dutta, Jadavpur University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The value of “Rare Earth Elements (REE)” which are often referred as rare earth metals is increasingly rising due to its many uses in today's high-tech world. Actually, REEs are used starting from miniaturization of electronics, to the enabling of green energy and medical technologies, supporting numerous of essential telecommunications and defense systems (Charalampides *et al.*, 2015; Dutta *et al.*, 2016; Schreiber *et al.*, 2016). REEs are the key ingredients of Cellular telephones, computer hard drives, electric and hybrid vehicles, and flat-screen monitors and televisions, significant defense applications include electronic displays, guidance systems, lasers, and radar and sonar systems. The amount of REEs used in high tech equipment is nominal but almost always significant to the unit's performance. REEs are called “technology metals” or “the seeds of technology” because of their unique magnetic, phosphorescent and catalytic properties. As per International Union of Pure and Applied Chemistry (IUPAC), rare earth elements are a set of seventeen chemical elements in the periodic table, specifically the fifteen lanthanides plus scandium and yttrium. Specific and compulsory uses of each rare earth elements are described in Table 1. Basically, REEs are divided into two categories based on their atomic number (Schreiber *et al.*, 2016; Suli *et al.*, 2017): Light Rare Earth Elements (LREE) having atomic number 57–63 (La to Eu) and Heavy Rare Earth Elements (HREE) having atomic number 64–71 (Gd to Lu). Minerals containing largely yttrium and HREEs include gadolinite, xenotime, samarskite, euxenite, fergusonite, yttrialite. Minerals containing predominantly LREEs include bastnasite, monazite, allanite, loparite, lanthanite, fluocerite, cerianite (Haque *et al.*, 2014). But, commercially used minerals or ore containing operable mines are bastnasite, monazite and xenotime. Rare earths are not actually rare rather they are available with broad geological distribution and their average level on earth crust is 150–220 ppm (Dutta *et al.*, 2016) which is almost equal or sometimes greater than any other metals mined for industries. Poor supply chain to fulfill the demand of rare earth elements for a nation creates the scarcity of REEs and make them as rare. The reasons are various. First of all, rare earth present in geological deposits in combination with other mineral, which makes the extraction process complicated, challenging and expensive. On the other hand, radioactive element like thorium and uranium co-exist with them; results radioactive emission on extraction of rare earth elements. Some mines are closed and not in use due to the environmental threat associated with exploration of REEs. Environmental concern is also associated with the processing steps of REE ore from mine into their elemental state. Use of acids and organic chemicals are the source of greenhouse gas (GHG) emission and environment footprint. Therefore, life cycle impact assessment (LCIA) is a necessary component of to operate REE production unit. Table 2 shows the few selected life cycle based environmental impact of few rare earth elements. Prediction and as well as speculation

Table 1 Industrial applications of REEs

Sl. No.	REE	Symbol	Atomic number	Use
1	Scandium	Sc	21	High-strength Al-Sc alloy, electron beam tubes
2	Yttrium	Y	39	Capacitors, microwave filters, glasses, oxygen sensors, radars, lasers, superconductors
3	Lanthanum	La	57	Glasses, ceramics, car catalysts, pigments, accumulators
4	Cerium	Ce	58	Polishing powders, ceramics, phosphors, catalysts, pigments, misch metals, U V filters
5	Praseodymium	Pr	59	Ceramics, glasses, pigments

Table 2 Carbon footprint of selected rare earth oxide production (impact analysis as per Australian indicator)

REOs	Primary energy (MJ/kg)	GHG (kg CO _{2-e} /kg)	Toxicity (^a DALY/kg) × 10 ⁻⁶
La	177	9.3	1.65
Ce	157	8.3	1.46
Pr	798	41.4	7.36
Nd	743	38.5	6.86
Sm, Eu, Gd (mixed oxides)	1074	55.6	9.89

^aDALY – Disability adjusted life years (unit of toxicity).

Note: Haque, N., Hughes, A., Lim, S., Vernon, C., 2014. Rare earth elements: Overview of mining, mineralogy, uses, sustainability and environmental impact. Resources, 614–635.

about the “peak oil” i.e., the theorized point in time when the maximum rate of extraction of petroleum is reached, after which it is expected to enter deadly turn down; but, similar type of study is also becomes inevitable for REEs and REOs because of increasing demand of rare earth elements and limited reserve of it. However, most of REE and REO are expected to be utilized in energy reduction, energy efficiency and renewable energy technologies. Consequently, most nations are motivated to secure REE by recycling or other preservation techniques and some countries relied totally on REE import. However, this trend is rapidly changing as China (largest producer and Supplier of REEs) government imposed restrictions on REE import (Haque *et al.*, 2014).

Recently, scarcity of energy and problems of environment become the major focus of global concern and thrust has been directed towards “sustainable development” in every nations. High and specified demand of rare earth elements for technological improvements and mitigation of energy issues are also acknowledged. But, problems related to abolishment between demand and supply of REEs creates large concern now-a-days. Moreover, environmental threats related to mining of REEs become the focus area. Practice of ‘green mining’ methodologies may result ‘green industries’ of REE. The objective of the article is to describe the review of the overview of green mining methodologies for REEs to overcome the threatening environmental aspect and to diminish GHG footprint.

Application of REEs

Use of REE in various sectors is considered as important tool for today’s advanced technological progress. The developed REO end-users markets consume mainly cerium (45%), lanthanum (39%) and yttrium (8.0%) (Charalampides *et al.*, 2015). Dysprosium, gadolinium, neodymium, and praseodymium oxides contribute the remaining 7.0% of total REOs demand (Charalampides *et al.*, 2015). REEs are used everywhere like in cell phones, laptops, televisions, hybrid cars, wind turbines, solar cells, hard disks and other many high-tech applications. Rare earth elements make the world’s strongest permanent magnets. These magnets are used in electronic motors to produce high power magnets in hybrid vehicles with smaller and light weight car. Miniaturization of hard disks used in electrical devices is also made by these powerful magnets. Neodymium and praseodymium are the REEs used in powerful magnets with little amount of dysprosium and terbium to allow them to retain their properties to higher temperatures too. REEs like europium, terbium and yttrium are used in energy efficient lighting (compact fluorescent lamps) and display panes (LEDs, plasma, LCDs) as phosphors. Cerium is used in catalytic converters which results better emission quality from a combustion engine used in automobiles. Emission of toxic gases like nitrogen oxides gets reduced by the use of RE in catalytic converter which helps to convert toxic nitrogen oxides to harmless nitrogen and oxygen, carbon monoxide to carbon dioxide and moreover oxidize unburnt hydrocarbons. Most of the cars now have these types of catalytic converters. Another important use of REEs is in rechargeable batteries. A mixed rare earth metal alloy is used as anode in NiMH battery; lanthanum is most widely used rare earth element in NiMH battery. Rare earths are directly used as catalyst in crackers used in oil refinery industries. On addition with glass, REO has the capability to enhance the glass property to absorb ultraviolet light by altering the refractive index. Yttrium is used in lasers. Neodymium and other REEs are used as dopants for the production of YAG lasers. The main industrial applications are described briefly listed in Fig. 1 (Dutta *et al.*, 2016). Even REs are added to aluminum, iron, steel and other metals to improve specific physical properties of alloys. REEs are doped with various compounds like ceramic glaze, barium titanate powder, ferrites for various types of improvement in their quality. REEs has great role in clean energy technologies like wind turbines, electric cars, solar cells and energy efficient lightening and rechargeable batteries. US department of energy (USDoE) assessed that REEs are widely used in various clean energy technologies and predicted (2010) that it need to grow significantly in next few decades for enhancement of use of renewable energy in different sectors. In order to evaluate the demand of REE using the present state of four technologies in 2016/2020/2025/2030, eight market scenarios are forecast including wind power, linear fluorescent lamps (LFLs), compact fluorescent lamps (CFLs), light-emitting diode (LED), electric vehicles (EV), electric bicycles, NiMH batteries, and catalytic converter (Kamenopoulos, 2016). The overview of the clean energy demand is presented in Table 3 (Kamenopoulos, 2016).

Distribution of REE

Though REE are relatively abundant in the upper part of earth crust but not always easy to exploration them commercially. The viability of exploitation usually depends on the geology, grade, tonnage, available processing technology and on associated cost.

Fig. 1 Commercial applications of REEs. *Source:* Dutta, T., Kim, K., Uchimiya, M., *et al.*, 2016. Global demand for rare earth resources and strategies for green mining. *Environmental Research* 182–190.

Table 3 Overview of global clean technology demand in 2016/2020/2025/2030

Year	Wind power (MW)	Lighting			Electric vehicle		Batteries	Catalytic converter (MW) (Million cars)
		LFL (Million Cps)	CFL	LED	Electric cars (car)	Electric bicycles	NiMH batteries (battery)	
2016	63,350	2142	1903	2675	750,000	35,000,000	580,125	95
2020	79,005	1604	1491	4828	21,400,000	35,500,000	1,252,900	110
2025	76,810	1116	662	5874	7,953,375	36,300,000	715,803	111
2030	107,488	776	294	7146	29,523,323	37,000,000	2,657,729	171

Note: Zhang, F., Dongyuan, Z., 2008. Synthesis of uniform rare earth fluoride (NaMF₄) nanotubes by in situ ion exchange from their hydroxide [M(OH)₃] parents, *ACS Nano* 3, 159–164.

The global reserves of REEs are estimated at 130 million tones (as per report of United States Geological Survey, USGS, 2016); but only 0.1% of total reserve is now in use (Kamenopoulos, 2016). China is the biggest player in REE production; control 99.8% of world REE production. United States, Brazil, Australia, India, Malaysia are the important producer of REE in world market scenario. An approximate recent estimate about REE reserves by country is shown in Fig. 2 and estimated capacity of world reserve country wise is depicted in Fig. 3. The majority of the global REE production comes from four minerals: Bastnasite, Monazite, Xenotime and Loparite (Zhou *et al.*, 2017). Bastnasite in China comprises the largest percentage of global REE production, followed by monazite in Australia and India, loparite in Russia, and xenotime in Malaysia (Zhou *et al.*, 2017). The world's most popular and largest RE mine in China, Bayan Obo (Inner Mongolia), was initially identified as iron ore mine; was mined REE for long time; but production has been reduced its major ecological and environmental impact. Actually, REE has potential market in different sectors like catalysis, polishing, glass, phosphorous and pigments, metallurgy, batteries, magnets, ceramics and others. Considering all aspects, operation in Bayan Obo started production in huge scale with some steps for environmental remediation. Another biggest RE mine is situated in US, located in Mountain Pass, California. Though environmental issues are there also, but recently it is undergoing expansion and modernization. As per USGS report, a gigantic REE reserve was identified in the Helmand Province, Afghanistan. Ion-adsorption clay deposits, alternative REE reserve, are available in Southern China which marks environmental footprint in Jiangxi which has 2.3 Mt ion-adsorption RE reserves (Zhou *et al.*, 2017). Environmental impact is comparatively lower than Bayan Obo and Mountain Pass in the Mount Weld mine in Western Australia and in Malaysia.

Rare Earths Production Steps

REE production can generally be divided into the following steps (refer Fig. 4):

- (1) Mining and extraction: Removal of REE containing ore or specific waste fraction.
- (2) Concentration and purification: To produce pure REE containing mixture for separation.

Fig. 2 Global REE reserve by country. *Source:* Kamenopoulos, S., 2016. Development of a framework and a decision support system for the sustainable exploitation of rare earth elements. Doctoral Dissertation.

A review of rare earth mineral processing technology. *Chemical Engineering Research Bulletin* 19, 20–35.

(3) Separation: To have different REE fractions.

(4) Refining: To produce a sellable product.

Rare earth resources are varied in their geology, mineralogy, and REE contents. A series of precise techniques are required to process various REE resources to extract commercially viable elements.

Mining and Extraction

Generally, rare earth mining can be open pit or surface mining, underground or leached in-situ (Haque *et al.*, 2014; Schreiber *et al.*, 2016; Suli *et al.*, 2017). A typical open pit mining is done considering ore composition, mining rate, stripping rate and rare earth oxide (REO) content. It is commonly employed in China, United States, and Australia. It involves taking out ores from the tunnels by blasting and transporting them to the surface for concentration of ore. If the ores are 100 m from the surface (Suli *et al.*, 2017) then only open pit method can be employed. Though this method is less expensive but usually not followed it leads large scars to the land surface and harmful to the environment too. It involves huge amount of water and energy usage. A large number of waste streams are also produced. In case of hard rock, both open-pit and underground techniques are followed like in Lovozero complex in Russia (Suli *et al.*, 2017). If the mineral is monazite type deposit then wet dredging is followed instead of dry mining. Though underground mines are considered as more expensive and unsafe than open-pit but still it is in use in some cases. In-situ leaching technique is followed in some special cases like for deposits in Southern China (Suli *et al.*, 2017).

Concentration and Purification

It is basically beneficiation process of RE bearing minerals for removal of undesired impurities from desired product by some physical means. Magnetic separation, froth floatation, gravity separation and followed by dewatering of minerals (thickening or drying) are followed in a sequential manner (as per the specification of the ores) to have purified ore sample for RE. All the physical separation is preceded by size reduction process. Suitable single or multiple physical separation steps are followed case wise as per composition of ore available. Table 4 indicates composition of an ore of Norra Korreudialite. It is evident that the RE ores are usually found to be combined with barite, fluorite, calcite, silicates and iron minerals which can be quite challenging to separate. The ores are crushed using double-stage jaw crusher first to a size less than 2 cm (Schreiber *et al.*, 2016; Suli *et al.*, 2017) and followed by grinding in a ball mill to finer size (40–100 μm) (Suli *et al.*, 2017). These finely ground materials are ready for next beneficiation steps like froth floatation, magnetic separation, electrostatic separation, gravity concentration, or a combination of all. According to Spedding's theory (Spedding, 1975), REEs have a series of electrons involving a shielded 4f sub-shell and these electrons have magnetic charge, and may results some degree of magnetism. If magnetic particles are present, magnetic separation becomes important before froth floatation unit. The ore-water slurry is prepared in a mixer and passed to froth floatation cell to separate the valuable metals and impurities. The depressant (include sodium silicate, sodium hexafluorosilicate, lignin sulfonate, or sodium carbonate) and collector chemicals (like hydroxamates, fatty acids, dicarboxylic acids, and organic phosphoric acids) are added respectively to prevent floating of unwanted mineral and to attach desired minerals with air bubbles respectively (Refer Fig. 5) The RE particles may require at least an estimated 40–100 μm size diameter for better attachment with the air bubbles and optimum froth floatation feed. If the minerals has huge specific gravity (from 4 to 7) (Suli *et al.*, 2017) then gravity separation is suitable to be applied. The enrichment in gravity settler or froth floatation cells may be up to 62%. The ore-water slurry is then de-watered using thickener and flowed by thermal process (e.g., drying) in rotary dryers or spray dryers.

The concentrated ore is then purified using chemical treatment methods to produce at least 90% purified product. There are two routes: acid treatment and alkaline treatment; combined known as 'cracking processes'. Sulphuric acid (H_2SO_4), hydrochloric acid (HCL) and nitric acid (HNO_3) are used in acid treatment process, while NaOH and Na_2CO_3 are commonly used in alkaline treatment. It is found that (Suli *et al.*, 2017) alkaline treatment is mostly applied in monazite and bastnasite (Suli *et al.*, 2017; Royen

Table 4 Ore composition of Nooakorr

Component	Mean value (%)
SiO_2	55.1
Al_2O_3	17.17
Fe_2O_3	5.35
CaO	3.17
MgO	1.31
Na_2O	9.00
K_2O	3.99

and Fortkamp, 2016) due to its phosphate and carbonate–fluoride content. Acid-roasting with sulphuric acid (H_2SO_4) at high temperature is used to remove fluoride (HF), sulfur dioxide (SO_2), sulfur trioxide (SO_3), and silicon tetrafluoride (SiF_4). Hazardous gasses including hydrofluoric acid (HF), acid sulphuric (H_2SO_4) and hexafluorosilicic acid (H_2SiF_6) will be adsorbed during the first and second scrubber before being released to the atmosphere. As acid treatment does not give a sufficiently clean product and does not recover phosphate of the minerals, caustic soda method becomes popular one. The acid treatment is currently apply at the Bayan Obo mine in China, but the alkaline treatment was apply by Molycorp at the Mountain Pass mine before the company closed in 2002. Various applied routes for various types' ore are described in Fig. 6 (Royen and Fortkamp, 2016). The leach solution from sulphuric acid digestion, contains other elements namely uranium (U), thorium (Th) and ferum (Fe). Thorium (Th) and uranium (U) are removed by following steps like sodium double sulphate precipitation, neutralization by ammonia hydroxide and neutralization by sodium oxalate. The caustic soda method begins with dissolving the mineral in concentrated sodium hydroxide at $140\text{--}150^\circ\text{C}$ to convert REE and thorium into their hydroxides (Suli *et al.*, 2017; Royen and Fortkamp, 2016). The solution is diluted with water which results precipitation of REE and thorium but phosphate remains in solution and can be recovered as tri-sodium phosphate (Royen and Fortkamp, 2016). Hydrochloric acid is used to precipitate REE selectively and thorium and other suspended material are removed by filtration.

Separation

The purified REE mixtures then undergo separation techniques to produce individual REEs. Due to having alike physical and chemical properties, it is very challenging to separate individual RE from each other. Some methods are followed to separate RE from the ores which are namely chemical precipitation (de Vasconcellos *et al.*, 2004; Panchula and Akinc, 1996; Queiroz *et al.*, 2002), reduction (Uda *et al.*, 2000), bio-sorption (Diniz and Volesky, 2005; Palmieri *et al.*, 2002; Kazy *et al.*, 2006), membrane extraction (Sugiura *et al.*, 1989; Kubota *et al.*, 1995), liquid membranes, solvent extraction (Yongqi *et al.*, 2008; Zhang and Dongyuan, 2008), ion exchange (Zhang and Dongyuan, 2008) and electro-winning (Enghag, 2004). However, supercritical, bio-sorption, electro-winning, solvent extraction and ion exchange are the five most standard methods for extracting REE. Solvent extraction or liquid-liquid extraction is the most popular large-scale separation method, usually carried out as a continuous multi-stage process of repetitive fractionation in a group of mixer settlers called “batteries” (Royen and Fortkamp, 2016). The REE-containing aqueous feed solution is first passed to a mixer to mix with an organic phase containing an organic solvation agent that forms complexes with REE ions. The ions are then extracted from the REE-enriched organic phase by moving it into contact with an aqueous solution where the ions have higher solubility. By adjusting the pH of the solution, scrubbing action can be done followed by solvent extraction to remove co-extracted contaminants from the organic phase. The most economical ion exchange techniques are employed to obtain high quality RE products either for electronic or analytical application. The organic extractant which are commonly used are di-2-ethylhexyl-phosphoric acid and 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (Suli *et al.*, 2017). Most researchers are interested in REEs by supercritical fluid (SCF) technique, in which, REEs extraction are expected to be improved by means of increasing the mass transfer between CO_2 and REEs and the rapid and complete removal of the solute from the solvent is reached by means of gasification of carbon dioxide at atmospheric pressure, after the extraction. Ion exchange can be used in the next to produce very pure REE. An ion exchange resin captures the REE ions and the elution of REE from them is done using suitable eluent solutions, often containing certain complexing or chelating agents with different affinities for different REE. But, ion-exchange methods are time consuming and commercially it is only used to produce a few of the heavy REE (HREE).

Fig. 6 Processing routes of extracting REE from different type's ore. *Source:* Royen, H., Fortkamp, U., 2016. Rare earth elements – Purification, separation and recycling. Report by IVL Swedish Environmental Research Institute.

Refining

It is basically a step of production of RE metal. Metals are produced by molten salt electrolysis and by metallothermic reduction methods (Enghag, 2004). It can results 99.99% purity of RE metals. Though the process is technically complicated and requires huge amount of electricity, but it is practiced well in China (Royen and Fortkamp, 2016). In metallothermic reduction, REO is treated with HF to form fluoride and removed along with calcium as liquid calcium fluoride. However, Sm, Eu, Tm and Yb have to low boiling points, so this process is not followed in this case and their oxides are reduced in a melt with metallic La, which has a very low vapor pressure. The reduced metals are vaporized and deposit on the walls of the tantalum container where the reaction takes place (Royen and Fortkamp, 2016). Barium can be used in place of calcium and mischmetal (i.e., a REE alloy typically composed of mostly of Ce and La with smaller amounts of Nd, Pr, other REE and iron) can be used instead of pure La. The main outputs of electrolysis process are CO, CO₂, C₂F₆, HF, CF₄ and dust (PM 2,5) with maximum amount of CO and high amount of CO₂ and dust too (Schreiber *et al.*, 2016).

Consequences of REE Mining and Processing

Rare earth mining and extraction procedures create enormous exploitation of earth's resources which results destabilization of soil and water ecosystems. One of the major concerns of REE mining from the primary ore deposits such as bastnasite and monazite is the resultant of radiological effects as REEs co-exist with radioactive minerals like thorium and uranium (Dutta *et al.*, 2016). REE mining directly affects some concerns like soil erosion, biodiversity loss, land use change, flooding, pollution of air, water and soil,

crop uptake of REEs and consequently leading to human health issues. It is worthy to mention that in-situ leaching lowers the ground water contamination, protects soil and vegetation. On the contrary, the expected environmental impact in relation to rare earth processing particularly linked with waste management and disposal of tailings which dictates importance to change in processing to recover rare earths from ores and other sources. The global warming potential impact or greenhouse gas (GHG) footprint of REE production is a serious concern today. The major donor to total GHG footprint is hydrochloric acid, followed by steam use and electricity. Overall 51% of GHG is due to use of energy in various forms (i.e., diesel, steam, fuel oil and electricity) (Haque *et al.*, 2014). The remaining minor elements are from other chemicals and transport. One report indicates that for the production of 1 tonne of REO in China are 60,000 m³ of waste gases, 200 m³ acidified water and 1.4 tonnes of radioactive waste (as most REE deposits contain uranium or thorium) (Royen and Fortkamp, 2016) are formed. The other important factor in relation with GHG footprint is the massive use of organic chemicals in solvent extraction step; requires the effort to reduce the use of organic chemicals to minimize disposal issues. Radioactive substance laden gases produced like sulfur oxides, hydrogen chloride, hydrogen fluoride and dust are the possible emission from REE processing unit which causes air pollution. Similarly, water contaminants are radioactive substances, heavy metals, acids, fluorides and large amounts of ammonium (Royen and Fortkamp, 2016). Aquatic eco-toxicity has a share around 22%–30% of the total impacts (Schreiber *et al.*, 2016). Above all, the environmental impacts depend on the ore grade and recovery of the particular REEs. The GHG footprint of separated oxides of REE from respective materials is shown in Fig. 7 (Haque *et al.*, 2014). Improvements on technologies starting from mining to processing of REEs are inevitable to sustain the REE industries in future days with minimal degree of environmental threats.

Mining of REE

The mining process of REE differs based on the type of ore being processed and the range of associated minerals. Bastnasite, Monazite and Xenotime are three significant rock forming minerals from which REE are extracted out. Bastnasite is a magma-derived fluorocarbonate mineral containing 65–75 wt% LREO and serves as major source of REE (Papangelakis and Moldoveanu, 2014). The two major sources in the world for lanthanides are bastnasite deposits at Mountain Pass, California, USA (devoted solely to REE production), and Bayun-Obo, Inner Mongolia, China (mined primarily for iron ore and REE as by-product). Monazite is a light phosphate containing rock associated with granites and beach sands in Australia, Brazil, India; comprising 55–65 wt% REO (Papangelakis and Moldoveanu, 2014). But, use of Monazite is decreasing due to radioactivity of thorium and radium. Xenotime is an yttrium rich phosphate containing rock with 25–60 wt% yttrium oxides; actually recovered as by-product of titanium, zirconium mining in Malaysia, Indonesia and Thailand (Papangelakis and Moldoveanu, 2014). Rare earth mining from its own ore (e.g., bastnasite and monazite) is not generally practiced because they occur as solid sediment and often lace up with radioactive element such as uranium and thorium. Radioactive elements production may occur simultaneously with extraction of rare earth elements. Thorium extraction always accompanies alpha particle emission, which can cause cellular damage when inhaled. Therefore, it is mandatory to have particular monitoring plan on REE extraction process.

Sedimentary Phosphate Deposits (Phosphorites)

Significant amount of REEs are found in marine sedimentary phosphate rock which entirely contained in francolite (Dutta *et al.*, 2016; Emsbo *et al.*, 2015). Compared to Chinese clay-type deposits, U.S. phosphate rock and its beneficiated equivalent are more

Fig. 7 Greenhouse gas footprint of some selected rare earth products. *Source:* Haque, N., Hughes, A., Lim, S., Vernon, C., 2014. Rare earth elements: Overview of mining, mineralogy, uses, sustainability and environmental impact. Resources 614–635.

enriched with REEs (total 500–2000 ppm of which 50–200 ppm HREs) (Dutta *et al.*, 2016). REE extraction from phosphate mining is encouraged now-a-days it does not associated with radioactive emission and radioactive waste production. On the other hand, REEs are easily extractable and extracted out concurrently when phosphate rock is dissolved in dilute sulphuric acid to produce phosphoric acid used for manufacture of fertilizers. Huge demand of phosphate fertilizers ensures the production of significant amount of REEs in an environmental friendly manner. Recently, apatite, another ore of phosphate deposits are investigated for production of REEs and results 0.1–1.0 mg/kg REO content. It is reported that 15% of total U.S. REE demand and specifically 65% of total U.S. HREE demand of 2014 is fulfilled by U.S. phosphate industry (Emsbo *et al.*, 2015). Actually, production of phosphate fertilizer from phosphate rock is in tough competition with REE production from phosphate rock because some phosphate occurrences suggest that REE can be mined more economically than phosphate fertilizers. In U.S., Palaeozoic phosphate deposits were identified (but not mined) (Emsbo *et al.*, 2015) which can be a future resource of REE. In Arkansas Love Hollow phosphorite deposits, 235 Mt of phosphate rock contains 1.3 Mt of extractable REEs of which 0.37 Mt are HREE which is roughly twice of HREE estimated for the South China clays (Emsbo *et al.*, 2015) and 60 times than Bokan deposit which yields 50% of REE projected global demand (Emsbo *et al.*, 2015). Therefore, abundance of phosphate rock and low-cost economic processing to produce phosphate fertilizer along with REEs manufacture in an environmentally friendly way makes the phosphate rock potential source to meet the global REE demand.

Ion-Adsorption Clays

In 1969, the ion-adsorption clays were first identified as novel rare earth ore in Jiangxi province (southern China) (Papangelakis and Moldoveanu, 2014; Refer: Fig. 8). Actually, three types of industrial grade REE ore (mixed bastnaesite and monazite, bastnaesite and ion-adsorption clays) are available in China among which 2.9% of total REE reserves comes from ion-adsorption clay (JinYang *et al.*, 2013); which meets 26% of China's total demand which has reached 35% in 2009 (JinYang *et al.*, 2013). Ion-adsorption clays have different REE content from that of bastnaesite and monazite and its REE distribution varies significantly from location to location, but they all appear to have much higher content of some highly valuable HREEs than bastnaesite and monazite. REEs present in ion adsorption clays are in the form of trivalent cations adsorbed on kaolin, which brings the relative simple and ease of extraction.

Ion-adsorption clays are formed due to physical, chemical and biological weathering of REE rich granite and volcanic rocks under humid, warm and slightly acidic conditions in subtropical zones. As per the report (Papangelakis and Moldoveanu, 2014), weathering crust are divided into four layers; (a) an upper humic layer of quartz, organic matter and soil with very low REE content, (b) strongly weathered layer enriched with REE along with kaolinite, halloysite, quartz and mica, (c) semi-weathered layer with kaolinite and sericite and (d) weakly weathered bottom layer with same mineral composition a host rock. Layer (b) contains most of the REE and layer (c) also contains REE but less in extent. Ion-adsorption clays contains 0.05–0.3 wt% rare earths out of which 60%–90% occurs as physically adsorbed trivalent cations which are easily extractable by ion-exchange leaching using inorganic salt solution of monovalent cations (JinYang *et al.*, 2013). Various methods of mining and corresponding leaching methods are followed in different cases. Heap, tank/pool leaching and in-situ leaching both are practiced in various places. In a specific inorganic salt solution, REEs are desorbed by substitution reaction forming monovalent ions and transferred into the solution as sulphates or chlorides, following a 3:1 stoichiometry and then precipitated as oxalate which then converts to REO and individual REEs are separated by dissolution in HCl and fractional solvent extraction. Sometimes ammonium bicarbonates are also used for precipitation of

Fig. 8 Ion-adsorption rare earth mining in Ganzhou, Jiangxi Province. Source: JinYang, X., Lin, A., Li, X., *et al.*, 2013. China's ion-adsorption rare earth resources, mining consequences and preservation. *Environmental Development* 8, 131–136.

REEs. Following Eqs. (1–3) are followed sequentially to convert REE containing ore to extracted REEs (Dutta *et al.*, 2016; Papangelakis and Moldoveanu, 2014):

Initially, opencast mining was followed with NaCl solution followed by oxalic acid precipitation (Papangelakis and Moldoveanu, 2014). But it resulted poor yield, poor product quality along with enormous overwhelming environmental impact like severe loss of vegetation and biodiversity, soil erosion and water contamination. Next, in batch and heap leaching, ammonium sulphate was used instead of NaCl which requires less in amount than NaCl due to increased desorption capabilities of NH_4^+ as compared to Na^+ and led to improved final product purity. But, this technology is also discarded as it is based on batch, heap leaching which lead to environmental problems due to mining-related deforestation and discharge of wastes. Continuous practice of heap leaching outcomes a great ecological and health damage in southern China. In-situ leaching replaces the heap leaching in China first and which is currently practiced to overcome the problems associated with it. In-situ leaching using ammonium sulphate gives best product quality and yield without surface vegetation clearing and soil disturbance. Fig. 9 describes the various routes of in-situ leaching methods followed in Southern China (Vahidi *et al.*, 2016). The basic principle of in-situ leaching is addition of leaching solution by injection directly into the natural orebody and recovery of the pregnant solutions for precipitation of REEs. Leaching holes with a depth of 1.5–3 m and diameter of ~ 0.8 m are drilled 2–3 m apart for injection of $(\text{NH}_4)_2\text{SO}_4$ (Papangelakis and Moldoveanu, 2014) at high pressure. It takes up to 400 days and ultimately 85%–90% of REE is extracted. Therefore, a comprehensive geological study of the site in order to determine hydrological structure of area, ore characteristics, grade and rock infiltration properties are prerequisite to carry out in-situ leaching.

Coal and Coal By-Products

There are different types of coals available and have their different types of ashes. Certain types of coal have fairly high concentration of REEs, on the order of 100 ppm. Coal and coal by-products are a potential source of REEs estimated amount in the range of 50 million metric tons (Charalampides *et al.*, 2015). It is reported by the researchers from West Virginia University and National Technology

Fig. 9 Flow diagram of ion-adsorption process followed in Southern China. Source: Vahidi, E., Navarro, J., Zhao, F., 2016. An initial life cycle assessment of rare earth oxides production from ion-adsorption clays. Resources, Conservation and Recycling 1–11.

laboratory that various valuable REOs are available in the acid mine drainage found at various coal mines. REEs are recovered (around 89%) by ionic-solvent extraction technique using ammonium sulphate and is then mixed the leached and filtered solution with an ionic liquid (1-butyl 3-methyl imidazolium chloride) and a deep eutectic solvent (2:1 urea/choline chloride, M/M) as lixiviants resulted in 80% and 71% recovery of REEs respectively (Dutta *et al.*, 2016). This ion exchange is more environmentally friendly and requires a reduced amount of energy. Ion exchange comprises rinsing the coal with a solution that releases the REEs that are bound to the coal. Actually, REEs can be obtained in cleaner way using coal and coal mine waste. The U.S. could soon decrease its dependence on importing valuable rare-earth elements that are widely used in many industries, according to a team of Penn State and U.S. Department of Energy researchers who set up a cost-effective and environmentally friendly way to extract these REEs from coal by-products.

Fly Ash From Fossil Fuels and Other Wastes

REE extraction process from fly ash of fossil fuels is recognized as less cost intensive than that mining from a raw product. Moreover, coal fly ash (CFA) contains full range of REE, whereas most mines have only a few types of these elements. This is why; many companies are discovering methods to extract REE from coal fly ash and considered the CFA processing as more economical and environmental friendly routes over traditional mining (Mayfield and Lewis, 2013). Study of fly ash from Jungar power plant, Inner Mongolia, China discovered that the concentration of REEs were greater in the finer sized fractions of fly ash than coarser one (Dutta *et al.*, 2016; Dai *et al.*, 2014). Still, the feasibility of recovering REEs from fly ash of fossil fuels are needed to be investigated more. Though there is no commercial leaching technology to leach REEs from coal ash but various laboratory methods are reported already. In acid leaching method, dilute sulphuric acid is used to dissolve REEs from fly ash. But, the efficiency of extraction is not good enough (highest leaching efficiency 45% and lowest 8%). Sometimes, instead of sulphuric acid, hot nitric acid may be used followed by solvent extraction using a mixture of tri-butyl phosphate and kerosene. In alkali leaching method, ammonium carbonate can be used to leach mainly yttrium.

Actually, South Korea has deficiency of REEs and imports of that from China are inevitable. Export of REEs from China is now limited; so alternative routes are devised in South Korea. Actually, coal ash samples from various industries like coal power plant has higher quantity of yttrium than coal. Therefore, coal ash samples are investigated already to find out higher range of REEs in South Korea (Thriveni *et al.*, 2013).

Sustainable Methods of Mining of REEs

Sustainable mining practices are nothing but to address the environmental, economic, health and social impacts and benefits of mining through the participation of investors. In the United Nations RIO + 20 conference (2012), resolution was taken that mining activities should maximize social, economic benefits and as well as effectively consider the negative environmental and social issues. Therefore, government needs strong initiative to develop, manage and regulate their mining industries for sustainable development. 'Green Mining' is best solution as it follows economic cycle and reduces environmentally objectionable emission. Demand of use of REEs in various applications is increasing day by day and mining of REEs has a long disagreeable past of environmental damage. Therefore, sustainable methods of mining (along with 'Green Mining') need to be practiced in a bigger shape.

REE Waste Management and Recycling Methods From Magnets, Batteries and Phosphor

Recovery of REEs from waste during production, landfills and end of life consumer products is referred as 'urban mining' (Dutta *et al.*, 2016) and recycling is needed to satisfy the increasing demand of REE and shortage of materials associated with supply issues and more specifically restriction imposed by Chinese authority. It ensures several benefits like lower environmental impact, less dependency on Chinese export and availability of radioactive contaminants free feed materials (Haque *et al.*, 2014). Moreover, it is experimented that discharge of REE waste causes deadly contamination of surface water and soil which can be minimized by 'urban mining'. A great challenge in recycling method lies in its low yield due to lack of established design or methodology to recover REE from wastes and it is believed that REE cannot be recycled back as it is always used in minute quantities. Among the post production waste or post-consumer disposed goods, used magnets, batteries, phosphor lightening and spent catalysts are important. Table 5 indicates the possible end-of use products to recycle specific REEs and their percentage recovery from the products.

Permanent magnets consist of neodymium-rich alloy with smaller amounts of Pr, Gd, Tb, Dy and other metals (Royen and Fortkamp, 2016). 30% of magnetic alloy simply become waste during production which is invariably recycled back. Permanent magnet containing electronic waste always shredded and melted down for recycling of other metals; REE present in it are oxidized and removed as smelter slag (Royen and Fortkamp, 2016). Various lab scale experiments are reported for efficient removal of REEs from NiMH batteries. In 2013, Honda and Japan Metals and Chemicals (JMC) proposed the recovering technique of REEs by use of molten salt electrolytes from NiMH batteries (Royen and Fortkamp, 2016). After collection of scraps, they dismantled and calcined-pulverized those into powder which are separated as different fractions. REEs are recovered as a dissolved phase in acid. Molten salt electrolysis is followed then to produce REE in metal form. In 2012, Rhodia (part of Solvay Group) took initiative to

Table 5 List of REEs recovered from end of use products (studied in 2016)

Order	Recycle	REE	% Recovery
1	Motors	Nd, Pr, Dy	82
2	Permanent magnets	Nd, Pr	93
3	Fuel cell catalysts	Pt	76
4	Phosphor lamps	Eu, Y	100
5	Oil refining catalyst	La, Ce	NA
6	NiMH battery	Nd, Sm, Pr, Ce	98.1
7	Fluorescent lamps	Eu, Y	99.9

Note: Dutta, T., Kim, K., Uchimiya, M., *et al.*, 2016. Global demand for rare earth resources and strategies for green mining. *Environmental Research*, 182–190.

recycle REE from old lamp phosphors in France (Royen and Fortkamp, 2016). Series of methods are followed to separate REEs from phosphor lamps like (Royen and Fortkamp, 2016);

- Froth floatation and physiochemical method: Under a controlled pH values (below 4.5), halophosphates are efficiently separates phosphor using this method. Though floatation is more difficult for separation of phosphors powders than mineral processing because of its complicated components and lower size, still it is in use. Density based separation also can be used using diiodomethane which has intermediate density among heavy phosphors and light halophosphates. Difference in magnetic susceptibility and photochemical reduction are also used for separation.
- Acid extraction method: It is an wet technique to recover REEs from waste spent fluorescent tubes. Nitric acid, hydrochloric acid or sulphuric acid are used as leaching agent. But, sulphuric acid is the most preferred among three acids. Some reports are (Hu *et al.*, 2017) available on use of supercritical carbondioxide containing tri-*n*-butylphosphate, nitric acid and water to separate yttrium and europium up to 100% (Hu *et al.*, 2017).
- Alkali fusion: it is basically high temperature, high pressure process. It is used after the acid leaching step to disintegrate the substances to prepare soluble fraction. NaOH, Na₂CO₃ and Na₂O₂ are commonly used fusion reagent.
- Solvent extraction: When water containing REE substance comes in contact with suitable solvent, REEs are separated very efficiently. It is reported that lanthanum (III), europium (III), and lutetium(III) were extracted by bis(4-acyl-5-hydroxypyrazoles) derivatives (Hu *et al.*, 2017). High recovery rate and good purity of the product are obtained by this method. A study in China reveals that to recover REEs from phosphor are 25% naphthenic acid ratio, 20% isooctyl alcohol, 55% sulfonated kerosene, phase comparison 1:1, and balance water phase pH 4.5; under such conditions, the REEs extraction yield is nearly 99.78% (Hu *et al.*, 2017). A new type of solvent, ionic liquid (IL) like functionalized IL betainiumbis (trifluoromethylsulfonyl)imide, [Hbet][Tf₂N] is recently used for selective dissolution of phosphor without leaching other constituents of waste powder like glass particles, alumina etc. ILs provide environmentally friendly and efficient alternative to traditional acid leaching.

There is no report yet to recycle REEs from spent catalysts. It is also regarded that substitution possibilities from energy efficient lightening systems (compact fluorescent lamp, LED, plasma display, LCD display) or catalysts in automotive and petroleum refinery are still complex and need further research.

Strategies for Promoting the Preservation of REEs

Rare earth elements are important constituent for clean energy technologies. Apart from energy sector, REEs are essential element for defense related technologies and weapons. Continuous supplies of REEs are absolute necessary for sustainable growth of a country. China is the only dominant global supplier of REEs. But, recently China has begun to close the export of REEs which creates shortage in supply of REEs in global market. It is reported that projected global shortage of essential REEs has started in 2014 and gradually it is increasing day by day. To tackle the China's monopoly in REE trading, administrative policies are developed and implemented to enhance recycling and preservation of the resources. Community awareness programs are also devised to improve the recycling and preservation of REEs. Several strategies are followed to preserve REE resources (Dutta *et al.*, 2016) like (i) developing strict industrial standards and laws for REE, (ii) avoiding illegal mining and centralized management of REE resources, (iii) developing integrated REE market pricing and distribution, (iv) arrangement of various programme to combat environmental problems associated with REE industries, (v) encouraging and implementing laws for recycling of REE from their potential waste and (vi) use of electro recovery solution using ionic liquids instead of acid leaching in conventional mining of REEs. All the strategies are basically judged based on diminishing carbon footprint by REE industries and balance between focused demand and supply of REEs.

Conclusion and Recommendation

The recent technological advancement is with the help of unique characteristics of REEs. Use of REEs in renewable energy applications is one of the most important aspects for growth of REE industries. Till date, China controls the global market of REE;

so it is necessary to identify alternative producers of REE to create competition in trading and as well as to fix the market price. Immediate adverse effects of REE mining like soil erosion, loss of biodiversity, flooding, pollution of air, soil, and water, and crop uptake of REEs, consequentially leading to human health issues; proposes the need of framework for sustainable development of REE mining projects which refers to five basic “overlapping” circles: economy, society, environment, technology, and geopolitics. Research is carried out to overcome the environmental issues related with conventional mining of REEs. Moreover, ‘green mining’ strategies are in practice which refers to “low production, high efficiency, low emission”. Recent global agenda is “exploitation of resources-environmental protection-sustainable development of mining area” for resource handling (Shi, 2012). According to ‘green mining’ initiative, 2012, millions of dollars are invested in mining research in countries like Australia, US. Exploring other sources of REE apart from its ore becomes the prime research topic in this area. It is worthy to mention that recycling and recovery of REE poses challenges in terms of energy to collection, reprocessing and reproducing products at specifications. It is sure that REE or products from REE will be the decisive factor of global economy in near future. But, over a longer time, nanotechnology may replace various critical materials like REEs or it may happen as they will require in lesser quantity. The exclusively environmental perspective of this review research paper is therefore addressing only one aspect of decision making and needs supplemented by economic and social assessment.

Hybrid Renewable Multigeneration: Low Carbon Sustainable Solution With Optimum Resource Utilization

Avishek Ray and Sudipta De, Institute of Engineering and Management, Jadavpur University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

According to the report of the Brundtland Commission, sustainable development is said to be “the development that meets the demand of the present without compromising the need of the future generations.” Presently, sustainable development is an important goal in the present days globally. But the scientists and the policy makers are facing severe challenges to find out the appropriate means to achieve the sustainable development goals. It is very difficult challenge for the energy sector to attain these sustainable development goals. This is because till date the entire world is dependent mainly on coal for electricity generation. Nearly 41% of the world's electricity is generated by coal. On the contrary the coal reserves of the world are depleting fast. Coal based power emits 0.975 kg of CO₂ for 1 kWh of electricity generated even in best practices (Hammond and Spargo, 2014). So continuous efforts are made to find out alternate sources of energy. The renewable sources of energy may be a better sustainable option than fossil fuels. However, renewable resources have serious limitations. The most prominent limitations are their generally dilute nature and intermittent availability. Developed technology till date is also not suitable to substitute fossil fuel based systems in full to meet the electricity demand of the world.

To develop a useful renewable energy system at a locality, the resource estimation of that particular location is very important. Battery storage may be integrated with renewable energy systems to accommodate intermittency. However, battery storage have limitations like high initial cost, lower capacity, lower life and disposal problem due to detrimental environmental effects. For a sustainable energy system cost effectiveness and environmental friendliness are two most important priorities. The term “greenization” of energy systems addresses simultaneously the issues of increasing the energy efficiency and the introduction of new energy systems under 3S criteria where 3S stands for “Source, Systems and Service” (Dincer, 2016). Service means the utility service which a particular form of energy gives to the society. Say for example the energy stored in oil is used in the transportation purpose. In this case oil is the source, using it in an engine is the system and transportation is the service. The greenization of the source includes the introduction of renewable. The greenization of systems includes process integration and better efficiency of the system. Thus a renewable based multigeneration addresses both of these issues simultaneously. Moreover multigeneration is also viewed as a more efficient method of utilization of natural resources (Serra et al., 2009).

In this article, the emergence of multigeneration as a low carbon technology is reported. Various aspects of design of multigeneration system is discussed. The importance of multigeneration as a potential option of sustainable energy system is also discussed.

Review of Low Carbon Technologies

In present practice, most of the secondary energy generation is through combustion of fossil fuels. These fossil fuels emit carbon dioxide and other greenhouse gases during combustion resulting to global warming. Hence, to reduce the global warming effect, low carbon technologies are inevitable. The low carbon energy technologies are mostly renewable using resources like solar, wind, biomass, tidal, geothermal etc. Till now renewable energy harvesting technologies are not so matured to meet the energy demand of the whole world. Moreover, renewable energy sources suffer from the serious limitations of generally dilute nature and intermittency. Technology is yet to be matured enough with proper devices for capturing and harvesting these resources of energy in a large scale. The share of different types of energy in the global energy mix is shown in Fig. 1. Though presently most important fuels in the generation of electricity worldwide are coal natural gas and oil, all of these resources are depleting fast and they emit greenhouse gases (GHG). Even the demand for coal increased at a rate of 6% per annum and the demand for oil by about 12% per annum in the last five years. So it is a need to develop alternate low carbon technologies for future energy sustainability. Prospective methods, presently visible for transforming the energy sector to be low carbon are shown in Fig. 2. Decarbonization, i.e., making the energy sectors a low carbon one may be done in a number of ways. More use of renewable resources of energy generally helps to achieve low carbon energy sector as renewable resources are either carbon negative (say solar, wind etc.) or carbon neutral, say biomass.

Higher energy efficiency, specifically for using fossil fuels is a decarbonizing measure as it helps to consume fewer amounts of input fuels for a required output utility. For fossil fuel based power plants efficiency improvement measures reduce the carbon footprint. On the other hand, renewable resources of energy are mostly intermittent in nature. These may not be available at the time when these are required. So either through storage or by means of hybridization the gap between demand and supply may be accommodated. At a particular time of the day, one or more resources may not be available but the others may be available for use. At night the solar energy may be absent but the biomass resources may be utilized for electricity generation at that time.

What is Multigeneration?

Multigeneration is the process of generating multiple utility outputs from one or more inputs. In multigeneration, process integration and intensification increase the efficiency of such an energy system. Several attempts have been made for

Fig. 1 Percentage share of different shares of energy in the global energy mix.

Fig. 2 Transition from Conventional Energy System to Sustainable Energy.

process integration for decarbonizing energy systems. Multi generation is one such advanced development of process integration. Fig. 3 shows the different development of multigeneration process through process integration at different levels. In a multigeneration system, there are multiple inputs and multiple outputs. Inputs are various sources of energy or material. Different types of inputs and outputs of a multi generation system are discussed in the later part of this article.

Fig. 3 Development of Multigeneration Concept.

Though electricity is a basic need, it is not the only need of the people. Several other utilities like potable water, fuels etc are also needs of the people. In coastal areas, drinking water is scarce. In many places due to remote terrain conditions it is very difficult to transport transportation fuels like diesel, petrol etc. Villages lying in the humid tropical regions also in need of cooling utility for temporary storage of perishable agricultural crops before selling in the market. So if all of these utilities can be combined in a single efficiently integrated system, then it is very beneficial from the societal point of view. Multigeneration systems if suitably designed may serve this purpose. Thus, multigeneration also finds its significance as a potential option of distributed generation to meet the local needs through optimum utilization of local resources.

Multigeneration as a Low Carbon Technology

Life cycle assessment (LCA) is considered as a potential tool for assessing the environmental impact of an energy system. Jana and De compared a multigeneration system with corresponding stand alone systems generating the same utility outputs for overall environmental impacts including carbon foot print (Jana and De, 2017). In multigeneration systems the process integration and the process intensification increase the energy efficiency of those systems. The high energy efficiency leads to the better utilization of resources and thereby reducing the carbon footprint of the system.

Planning and Design of Distributed Multigeneration Systems

In distributed multigeneration systems local resources are used as inputs. Suitable conversion technologies to deliver utility outputs from these inputs are efficiently integrated in multigeneration systems. Basic factors and steps to be considered for the design of a multigeneration system are illustrated in Fig. 4. For designing renewable energy based multigeneration systems, locally available resources at a particular place have to be assessed. After the resource assessment, suitable available technologies are to be identified that can be integrated efficiently for conversion of available resources to desired utility outputs is chosen. After this the electricity demand as well as the other utility demands like potable water, bio fuels etc are assessed.

Fig. 4 Formulation of a multigeneration design problem.

Then, the feasibility of the system is studied in that particular location from the environmental and the socio economic viewpoints. The final design of the system thus evolves based on the combined technical, environmental and the socio economic optimum performance of the system.

Possible Options of Renewable Energy Based Systems

The possible renewable energy resources available for input to the multigeneration systems are shown in Fig. 5. Unlike the fossil fuels, these are not feasible to be transported for distant use. So, the renewable based systems have to be designed only after assessing the duration and the amount of availability of the locally available renewable resources. Moreover, renewable resources are mostly intermittent and may not be always available when there is a demand for it, i.e., at the time of need. The demand of energy services identified in the load curve does not always match with the availability of renewable resources. The need of storage and/or hybridization of several renewable resources depending on the local needs thus arise.

Resource Utilization and its Relation With Low Carbon Energy Systems

Energy is an essential service for the growth of any community. Useful secondary energy is generated from naturally available primary resources. Resources are harvested using suitable conversion technologies to yield secondary energy. The maximization of the resource utilization is the key issue for the design of green and sustainable energy systems. This maximization of resource utilization may be achieved through increasing the efficiency of the energy conversion methods, more utilization of locally available resources available at a particular location etc.

Advantages and disadvantages of renewable energy systems

Renewable energy systems have following general advantages.

- (1) The renewable energy systems emit no or low greenhouse gases (GHG) for generation of energy.
- (2) The renewable resources are not depleting.
- (3) It is almost available at all parts of the globe though in different forms and concentrations at different locations.

In spite of all these advantages, the renewable sources of energy suffer from severe limitations like intermittency of availability and dilute intensity. For renewable energy systems, energy can be generated only when the resources are available but not necessarily when it is demanded. Hence storage is inevitably required to get 100% reliable power supply utilizing renewable sources. Till now the mostly used form of electricity storage is the electrochemical storage i.e. to store

Fig. 5 Possible options of renewable energy inputs for multigeneration.

electricity in a battery. But the electrochemical storage has capacity as well as environmental and economic limitations. High cost of the batteries makes the system cost high. Batteries are to be generally replaced after five years whereas most of the renewable energy systems have a life of about twenty years or more. Moreover, the disposal of the batteries is also not environmentally benign. Due to intermittency of availability of primary energies, renewable energy systems are not capable to deliver energy services as per the load curve. Using a single type of energy, Fig. 6 shows links between supply-demand, storage and hybridization in renewable based multigeneration systems. More demand than supply in a renewable based multigeneration in any time may be accommodated by power from a storage device like battery. Alternatively non availability of one form of renewable energy may be compensated by another available form if several forms of inputs are integrated i.e., 'hybridized' in a multigeneration. For example, during evening hours the sun is absent but the demand is high. At this time the electricity may be supplied from the battery or from other sources like wind, biomass etc which is available at that particular site. On the contrary, another situation may arise that the electricity generated from the available resources is higher than the instantaneous demand. In this case either the electricity may be diverted to any storage device to be used later during higher demand of it or the resource may be utilized to produce some other utilities like chemicals, biofuels etc. For example, the biomass gasifier generates syngas for power generation. The size of the gasifier and the biomass feed rate is fixed. But if the electricity demand is low, then the total amount of syngas generated at that instant may not be needed to produce electricity. For such cases a fraction of the syngas may be diverted to produce bio fuel like ethanol. This is done in a system called multigeneration.

Fig. 6 Schematic diagram showing links of storage, hybridization and multigeneration.

Table 1 Application of numerical algorithms in renewable based polygeneration systems

Author (year)	Algorithm used	Input	Output

Siddiqui and Dincer (2018)	Solar energy (Thermal)	Electricity, Potable water and hydrogen

Optimization of Multigeneration System

The economic operation of a multigeneration system needs a proper sizing of components considering the availability of local resources. Thus application of suitable optimization algorithms for the proper sizing of the multigeneration system is also important from the resource utilization point of view. In [Table 1](#), a few optimization algorithms used in renewable energy based multigeneration systems is shown. For optimization of renewable based multigeneration system, both linear programming and mixed integer linear programming are found suitable. Also, heuristic optimization methods like particle swarm optimization algorithm and multi objective evolutionary algorithm have also found its application. In majority of the multigeneration problems, multi criteria optimization is used.

Case Studies

Renewable based multigenerations mainly uses solar, biomass, wind and in some cases geothermal energy or a combination of these forms of energy i.e., several energy resources are hybridized. The outputs are electricity, heating, cooling, hydrogen, potable water and others. In [Table 2](#), a few examples of multigeneration systems with the inputs and outputs are given. The inputs are dependent on the resources available at a particular place and the outputs are decided to cater to needs of people based on socio-economic status of the local people. Suitable technologies are selected to for harvesting the resources into useful energy services. In the renewable based multigeneration systems, mostly solar and biomass resources are used. Mostly solar thermal route of energy conversion is used for the multigeneration systems as it is the convenient solar energy form for system integration. The biomass conversion technology mainly depends on the type of biomass available. The wet biomass is subjected to biochemical conversion i.e., bio-methanation and the dry biomass is subjected to thermo chemical conversion say, gasification.

Conclusion

Energy generation is done from naturally available resources. Resource management is an important aspect for the proper energy management and greenization of energy systems. Process integration is an efficient way for the proper energy management of a system. The levelized cost of electricity is also decreased by the application of the multigeneration system. The life cycle assessment is considered as an efficient tool for the assessment of the environmental performance of a system. The life cycle assessment of a multigeneration system also shows that the environmental load of a multigeneration system is lower than the sum of the environmental loads generating the same utilities. Moreover electricity is not the only need of the villagers. Other utilities like potable water, biofuels etc are also needed. If a single integrated system can give all these utilities along with electricity then it is a low carbon sustainable solution and beneficial from the socio economic point of view too.

Innovations in Variable Frequency Drives and its Implication in Reducing Carbon Footprint

Jitendra Saxena, The Institution of Engineers, Kolkata, India

Binoy K Choudhury and Krishna M Agrawal, Indian Institute of Social Welfare and Business Management, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

As reference to U.S. Energy statistics, industry accounts for more than 40% of the world 14,400 TWh (billion kilowatt hours) electricity. In Industrial sector above 50% of all electricity consumption is generally due to electrical drives (Hopper, 2007, 2006; Siemens, 2019a; see "Relevant Websites section"; Hossain *et al.*, 2017; SEEMP, 2012; Shahan, 2011; Siemens, 2019b; Su *et al.*, 2014b; Swamy, 2017; Verma *et al.*, 2010). United States, the distribution of industrial motor- system energy is 25% for pumps, 14% for fans, and 16% for compressed air (Su *et al.*, 2014a; Neufeld *et al.*, 2014; Hopper, 2007; Su and Yu, 2013). A case study reported in 2011 that globally 45% of all electricity used by electric motors (Shahan, 2011; Siemens, 2019b; Su *et al.*, 2014b; Swamy, 2017; Verma *et al.*, 2010). Besides industry, motors are major energy consumption electrical devices in HVAC in buildings, electric traction, electric vehicles, and many house hold utilities, such as, mixer, grinders, washing machines, etc (Su and Yu, 2013). As many of such uses have been increasing exponentially in recent years, the share of motors' electricity use would be increasing unless it is managed through efficient control such as VFDs (Hopper, 2007; Drews *et al.*, 2012a; Hopper, 2006; Schmehl *et al.*, 2014; Verma *et al.*, 2010; Hart, 2012; Rasanen *et al.*, 2012; Verma *et al.*, 2010; Yaskawa, 2019). 50% of world motors are installed in USA, European Union and China. Smart motor systems single-handedly could save 1718 TWh of electricity annually which is counterpart to the total electricity generation of 286 nuclear power plants globally (Hopper, 2007, 2006; Siemens, 2019a; see "Relevant Websites section"; Shahan, 2011; Siemens, 2019b; Su *et al.*, 2014b; Swamy, 2017; Verma *et al.*, 2010).

Variable speed drives for industrial utilities and applications are used for two main focal points: significantly to improve the efficiency of motor by driving the equipment by reference speed to variable load and to allow precise and continuous process control over a broad variety of speeds (Hopper, 2007; Drews *et al.*, 2012a; Hopper, 2006; Schmehl *et al.*, 2014; Verma *et al.*, 2010; Yaskawa, 2019). Centrifugal fans, blowers and pumps have been premeditated to meet the maximum load but actually function at reduced load after extended period of time leading to energy inefficiency (Shahan, 2011; Siemens, 2019b; Su *et al.*, 2014b; Swamy, 2017). Reports have stated that carbon dioxide is the important factor of the process. Carbon dioxide (CO₂) generated as the consequence of electrically operated industrial machines predominantly leads to global warming (Liu, 2018; Carbon trust, 2018; Price *et al.*, 2001, 1999; Jindal Steel Works, 2019). In an effort to minimise CO₂ emissions from industry, this article is analysing industrial electric motors equipped with variable frequency drives as the means of reducing CO₂ emissions (Price *et al.*, 2001, 1999; Shahan, 2011; Siemens, 2019b; Su *et al.*, 2014b). Electrical operated machines such as pumps, fans or compressors used in an industrial applications, are obsessed by electric drives. Thus, mitigating the efficiency and saving the energy usage of as well as mitigating CO₂ foot prints and its effects generated by the use of electrically operated devices like motors, pumps and motors are vital factor in recuperating and mitigating overall industrial performance and utility (Jindal Steel Works, 2019). Article give a learning paradigm and in depth study of carbon footprint and its negative effects, with significant features of variable frequency drives (MEFCC, 2018, 2015; Liu, 2018; Carbon trust, 2018; Olivetti *et al.*, 2013; see "Relevant Websites section"). High end applications of technologies have significant prospective to reduce significantly industrial energy use. Industrial energy use could be more efficient with the judicious application of latest energy conservation technologies, such as, variable speed drives in motors, energy efficient motors, energy-smart controls & systems for compressors and waste-heat in processes, etc. A variable frequency drive is an electronic driven power converter that predominantly generates a multi-phase, variable frequency output that can be used to operate a standard AC induction motor, and to transform and control the motor's speed, torque and mechanical power output. Variable frequency control technology has been proposed and applied to ship power pump load energy efficiency optimization (Giannoutsos and Manias, 2015a, 2013; SEEMP, 2012; Harrington, 1992; Brater *et al.*, 1996; Rishel, 2002; Su *et al.*, 2014a; Drews *et al.*, 2012b; Shahan, 2011; Siemens, 2019b; Su *et al.*, 2014b, 2016b; Su and Yu, 2013; Swamy, 2017; Su *et al.*, 2016a; Gaerke and Hernandez, 2015) in order to meet international electrical standards law and regulations, as well as energy conservation management requirements (SEEMP, 2012). Marine engineering systems are electrically complex system however, when sensing element fails, the workload of engineers for reliability and electrical safety increase. This is especially true when power pump equipment stops functioning due to a motor fault and the ship operation and navigational safety are negatively affected (Brater *et al.*, 1996; Rishel, 2002; Neufeld *et al.*, 2014; Siemens, 2019a). The efficient operation characteristics of power pumps under variable frequency control and drives will assist operators in smooth running and minimum outage time for marine engineering equipment operations and high reliability (SEEMP, 2012). The ship power pump load can be divided into deck machinery and engine room machinery according to the specific objectives (Harrington, 1992). The pumps, which can be categorised into four types according to their operating characteristics, include the centrifugal pump; rotary pump, piston pump and ejection pump (Brater *et al.*, 1996). The centrifugal pump is the one most commonly used on ships, and its operation methodology can be categorised as open or closed systems (Rishel, 2002). In an open system centrifugal pump, the fluid communicated by the pump performs an external flow between the equipment and the outside environment. Typical open marine pumps include the ballast pump and the seawater cooling pump. In a closed centrifugal pump, the flipper forms an internal circulation between a pipeline system and the equipment (Neufeld *et al.*, 2014).

These pumps include the fresh water cooling pump, M/E jacket cooling fresh water pump, lubrication oil pump and auxiliary boiler feed water pump. Various methods have been proposed for controlling open pumps by means of variable frequency drives (VFDs) (Hopper, 2006; Schmehl *et al.*, 2014; Su *et al.*, 2014a; Verma *et al.*, 2010; Giannoutsos and Manias, 2015a; Brater *et al.*, 1996; Siemens, 2019a; IEEE, 2014, 2010; Liu, 2018; Carbon trust, 2018; Rasanen *et al.*, 2012; Yaskawa, 2019; Hart, 2012; Shahan, 2011), those proposed for closed pumps (Rishel, 2002; Neufeld *et al.*, 2014; Su *et al.*, 2014a) have mainly focused on onshore power applications, with in depth literature regarding problems for closed pumps driven by VFDs in marine vessels or offshore power systems. This specific application offers major energy savings if applied in many industrial applications. Policy and strategic makers responded by introducing restrictions on carbon dioxide (CO₂) as it is the largest constituent of anthropogenic GHG emissions. This creates challenges for the energy intensive industrial sectors to manage their carbon footprint.

Different technologies related to CO₂ emissions as per Indian perspective are mitigated and discuss and Iron and steel industry as designated consumer is taken as case study in this article (MEFCC, 2015, 2018; Jindal Steel Works, 2019).

Carbon Foot Prints With Energy Use and Carbon Dioxide Emissions by Process in U.S. Steelmaking

For our detailed referral case study of the U.S. iron and steel industry, we focus on a small subsystem of the industry, blast furnaces and steel mills (SIC 3312) (IEEE, 2014; MEFCC, 2015; MEFCC, 2018). The main energy usage processes for integrated steel production are sinter-making, coke-making, iron-making, steel-making. Only the steelmaking step is used for production of secondary steel. Following steel production, energy is used for casting, hot rolling, cold rolling, and finishing. In 1994, integrated steel mills in the U.S. produced 55.4 Mt of steel and secondary steel mills produced 35.87 Mt, for a total U.S. production of 91.3 Mt. **Table 1** gives the referral view of Energy saving synergy major with different energy management strategies in iron and steel industry as per USA statistics **Table 2** gives Primary energy use for integrated steel making was about three times more than energy use in secondary steelmaking, consuming 1439 PJ compared to 425 PJ. The primary energy intensity of integrated and secondary steel production in 1994 was 26.0 GJ/t and 11.8 GJ/t, respectively, for a total sector primary energy intensity of 20.4 GJ/t. Total carbon dioxide emissions from steel-making in 1994 were 34.4 Mt C, with 80% of these emissions from integrated steelmaking. The carbon dioxide intensity of integrated steelmaking was 0.5 tC/t crude steel while the carbon dioxide intensity for secondary steelmaking was 0.2 tC/t crude steel, resulting in a total sector carbon dioxide intensity of 0.4 tC/t crude steel (Su *et al.* 2016a,b; IEEE, 2014). The above facts and figures give a specific data of carbon foot prints in Iron and steel industry and its effects. Iron and steel industry plays a vital role and major focus area in the field energy saving strategies by using variable frequency drives and its effects by CO₂. Implementation of VFD for Industrial process plant and carbon dioxide emissions can be reduced in one of the three methods, reducing energy and carbon produced from combustion by energy integration, reducing carbon from the fuel itself by the use of low footprint fuels and carbon storage and sequestration.

Operating and capital costs are calculated on a crude steel basis according to the same procedures as fuel and electricity savings. Allocation of the share of production to which each assess is applied was based on a multiplicity of information sources on the U.S. iron and steel industry in 1994 and expert decision. Finally, carbon dioxide emissions minimization and reductions for each measure were calculated based on a weighted average carbon dioxide emissions coefficient (tC/GJ) for each procedural step.

Variable Speed Drives for Flue Gas Control, Pumps, Fans

Based on referral studies in the UK, we assume that electricity savings of 42% are feasible through the use of variable speed drives (VSDs) on pumps and fans (Energy Star, 2019). Previous studies reveals that this technology can be applied to 5% of electricity use in integrated steel making, resulting in a savings of 0.04 GJ/t crude steel. Based on a 3.25 year payback of an installed system in the UK and assuming an electricity price of 3 pence/kWh, we calculate the costs to be \$1.3/t product. This equals a payback period of 3.4 years under U.S. 1994 conditions. Programmed heating instead of conventional constant heating of the coke ovens ensures optimization of the fuel gas supply to the oven at the various stages of the coking process and reduces the heat content of the coke before charging. Use of programmed heat can lead to fuel savings of about 10%, estimated to be 0.17 GJ/t coke. Small capital costs regarding the computer control system for the coke oven are included. Review studies reveals that the costs to be \$75K per coke battery for a large energy management system, which is equivalent to approximately \$0.23/t coke for the coking capacity of the integrated steel mills (excluding merchant coke producers). This measure is also applied to 100% of U.S. coke production in 1994.

Variable Speed Drive Coke Oven Gas Compressors

Variable speed drive coke oven gas compressors can be installed to reduce and minimise compression energy. Coke oven gas is generated at low pressures and is pressurized for transport in the internal gas grid. The coke oven gas flows vary over time due to the coking reactions. Installing a variable speed drive system on a compressor at a coke plant in the Netherlands saved 6–8 MJ/t coke, at an investment of \$ 0.3/t coke. Coke dry quenching is an alternative to the traditional wet quenching of the coke, and this process reduces dust emissions, improves the working climate, and recovers the sensible heat of the coke. Dry coke quenching is typically implemented as an environmental control technology. Various systems are used in Brazil, Finland, Germany, Japan, and Taiwan, but all essentially

recover the heat in a vessel where the coke is quenched with an inert gas (nitrogen). The heat is used to produce steam (approximately 400–500 kg steam/t), equivalent to 800–1200 MJ/t coke. The steam can be used on site or to generate electricity. For new coke plants the costs are estimated to be \$50/t coke, based on the construction costs of a plant in Germany.

Variable Speed Drive on Ventilation Fans

The BOF process is basically a batch process. The volumes of flue gases vary widely over time, making variable speed drives an option. Large fans are used in the BOF plant to control air quality. At Hoogovens the use of variable speed drives has been shown to save power (Energy Star, 2019) in the BOF, reducing the power demand by approximately 20%, or 0.9 kWh/t crude steel. With total costs of \$1M (1988) the investment costs are \$0.2/t crude steel. We assume that such variable speed drives could be used in all U.S. BOF steelmaking facilities. Improved process control (neural networks) can help to reduce electricity consumption beyond that achieved through classical control systems. For example, neural networks or “fuzzy logic” systems analyze data and emulate the best controller. For EAFs, the first “fuzzy logic” control systems have been developed using current, power factor and power use to control the electrodes in the bath. The average power savings are estimated to be up to 8% (or 38 kWh/t), with an average increase in productivity of 9%–12% and reduced electrode consumption of 25%. The actual savings depend on the scrap used and the furnace operation. Furnace maintenance costs are reduced as well. We assume an average efficiency improvement of 30 kWh/t (or 0.1 GJ/t).

Table 2 Energy use and carbon dioxide emissions by process in U.S. steel production, 1994

Process stage	Fuel (PJ)	Electricity (PJ)	Final energy (PJ)	Primary energy (PJ)	Carbon dioxide emissions (MtC)
Integrated steelmaking

Flue Gas Monitoring and Control

Flue gas monitoring and control using variable speed drives can reduce the energy use for the flue gas fans, reducing the heat losses in the flue gas. The flue gas flow varies over time, which makes the use of variable speed drives possible. Flue gas VSDs have been installed in various countries (e.g., Germany, UK). The electricity savings are estimated to be 15 kWh/t, with a payback period of 2–3 years (Energy Star, 2019; Hart, 2012; Siemens, 2019a,b). We estimate the capital investments to be \$2/t, and apply this measure to all furnaces with a size of 100 t or larger, equivalent to 50% of the U.S.

Controlling Oxygen Levels and Variable Speed Drives on Combustion Air Fans

Controlling oxygen levels and variable speed drives on combustion air fans on the reheating furnace helps to control the oxygen level, and hence optimize the combustion in the furnace, especially as the load is variable. The savings depend on the load factor of the furnace and control synergy applied. Two cases from the UK steel industry demonstrate the various techniques. Implementing a variable speed drive combustion fan on a walking beam furnace at Cardiff Rod Mill (UK) reduced the fuel consumption by 48% with a payback period of 16 months (1985 UK conditions). Another example (without installing variable speed drives) is a walking beam furnace for reheating billets, saving approximately 2% on fuel use, with a payback of one year (Energy Star, 2019). Reported referral energy savings of 10% equivalent to 0.33 GJ/t product, at an investment of 0.5\$/t product. A systematic approach to integrate reduced carbon dioxide after implementing VFD within an industrial park with manifold carbon emitting streams and the potential carbon utilization options (sinks) that may exist. The technique identifies the least possible cost integration options to attain a given footprint reduction target and decides which sources are preeminent captured together with their provision to the various utilization options. It determines if the captured carbon dioxide should be purified and takes into account costs of carbon capture, carbon transportation between sources and sinks as well as costs associated with the utilization processes.

Some of the main cost-effective energy saving measures for secondary steelmaking includes improved process control and carbon dioxide reduction is given in Table 3. Energy integration on an individual process or across multiple units that is primary steel making and secondary steel making has been applied to reduce carbon footprint. Many strategies used graphical methods to apply energy integration in order to achieve carbon emission target.

We identified cost-effective energy savings of 104 PJ and carbon dioxide emissions reductions of 1.5 MtC of carbon dioxide for secondary steelmaking in 1994 which represents 6% of total U.S. steelmaking energy use and 4% of total carbon dioxide emissions as shown in Table 4. More in depth work has emerged in terms of solving the problem of carbon dioxide generation mainly focus from energy integration point of view that later expanded to include multiple processes for Iron and steel plants or for different Industrial plants.

In the hot strip mill, recuperative burners in the rolling mill, improved process control in the EAF, and preventative maintenance.

These methods were aimed to reduce carbon dioxide generation as results of combustion thus targeting a reduced amount of energy use and new efficient designs. Other methods looked at cutting carbon dioxide from the resource itself while maintaining the energy condition. Nevertheless, these methods try to limit carbon production; they do not pact with the expected produced carbon. While the prospects of applying renewables into the energy grid is appealing, the move in industry towards their

Table 4 Summary of cost-effective 1994 energy savings and carbon dioxide emission reductions

<i>Steelmaking sector</i>	<i>Crude steel production (Mt)</i>	<i>Reduction in energy intensity (GJ/t)</i>	<i>Reduction in primary energy use^a (PJ)</i>	<i>Share of total U.S. iron and steel primary energy use (%)</i>	<i>Reduction in carbon dioxide emissions (MtC)</i>	<i>Share of total U.S. iron and steel carbon dioxide emissions (%)</i>
Integrated	55.4	4.3	236	13%	5.0	15%
Secondary	35.9	2.9	104	6%	1.5	4%
Total	91.2	3.8	341	18%	6.5	19%

^aPrimary energy is calculated using a conversion rate from final to primary electricity of 3.08, reflecting the difference between an average power plant heat rate of 10,500 Btu/kWh and a site rate of 3412 Btu/kWh, including transmission and distribution losses.

Note: Energy Star, 2019. Available at: www.energystar.gov (accessed February 2019).

adaptation might be slow as fossil fuels are currently the most used energy sources. Therefore, there is a requirement to apply a methodology that resolves the carbon production issue. This has been demonstrated through the study of carbon capture allocation between sources and sequestration sinks.

Attempts to allocate carbon dioxide in utilization sinks across processes have not been studied before. The concept of using the waste or emissions elsewhere as in natural ecological systems stems from Industrial Ecology's (IE), Eco-Industrial Parks (EIP).

Variable Frequency Drives in Motors

The macro field of Motor Drives has gained significant importance in recent years. One reason is the availability of high speed processors needed for extensive analytical calculations to achieve good performance and control of AC motors. In addition, extraordinary progress in power semiconductor devices cannot be ignored. An important reason for the extensive use of variable frequency drives (VFDs) in industrial and commercial applications is the significant energy savings that it enables due to the possibility of operating AC motors at variable speeds. However, in much industrial application, motors are made to run at rated speed with no need for speed control. Such operations do not capitulate any energy savings and in turn one has to account for the power loss in the VFD. A Silicon controlled rectifier (SCR) based

technology soft starter may be a better option in such cases. There are other applications where the use of VFD yields significant energy savings. In these applications, there is ample opportunity for improving system efficiency as will be discussed in the article.

In addition to brainstorming ideas to improve system efficiency in a cost effective manner, innovative topologies will be put forward that can result in optimal use of power semiconductor devices to achieve multiple tasks as will be explained in this article. In regenerative or bidirectional power flow applications, typically an LCL filter is used for interfacing the PWM frontend rectifier to the AC grid. In these industrial applications, predictably there is large circulating current through the filter capacitor even when the regenerative unit is not in working. There is power loss associated with this circulating current and in some cases, this current can also interact with other nonlinear loads on the system and can trigger system resonance. In many applications, VFDs need output filters to reduce the dv/dt experienced by the motors at large distances from the drives. In addition, common mode issues need to be taken care of to reduce radiated and conducted EMI noise. Ideas to achieve these multiple demands in an integrated filter section have been also discussed in the article.

Input Current Harmonics and System Efficiency

VFDs depicts nonlinear current from the AC source because of the presence of a three-phase AC to DC rectifier front end and a large DC bus filter capacitor. When distorted current flows through the system impedance, there is distorted voltage drop across the impedance, especially in weak AC systems. When distorted voltage drop across the system impedance is added to the system voltage, it results in voltage distortion. Many researchers have sought to reduce the effect of voltage and current harmonics in the power system (Swamy, 2017; Giannoutsos and Manias, 2013,2015a; SEEMP, 2012; Gaerke and Hernandez, 2015; Harrington, 1992; Brater *et al.*, 1996; Rishel, 2002; Su, *et al.*, 2014a; Neufeld *et al.*, 2014).

Voltage harmonics can negatively affect other sensitive loads on a given AC system. Current harmonics results more power loss in the power delivery equipment. Examples of power delivery equipment include power system transformers, feeders, circuit breakers, etc., around the world. Pumps and fans are by far the largest application of variable and constant frequency AC drives. The applications include boiler ID/FD fans and feed pumps, tunnel ventilation, sewage and water pumps, variable fluid flow in process control, drying or cooling by air, compressors and fans in air conditioning and refrigeration, ship propulsion, gas and fuel line compressors, etc. Presently, the artificial intelligence tools, such as expert system, fuzzy logic and neural network are showing performance impact on variable frequency drives. Designing of Filters with correct insulation is key points for study and professional using VFD's in Industries should have technical discussion with vendors.

The affinity Laws (also called the cubic Laws) states that pump output or flow are directly proportional to the speed of the pump. Therefore, to produce 50% flow, the pump would be run at 50% speed. At this operating point, the pump would require only 12.5% of rated horsepower ($0.5 * 0.5 * 0.5 = 0.125$ or 12.5%). From a mechanical point of view, bearings run at reduced speeds typically last much longer than their full speed counter-parts. "Soft Start" is a mechanism which can be achieve after installation of Variable frequency drives and for the operation of mechanical dynamic equipment (Su *et al.*, 2014a). A electrical load covers various types of electrical equipment, including power pumps, lighting equipment, communication and equipment load. The power pump and motors is the major user, accounting for about 70% of the total power consumption in Industries. Before deciding which motor VFD to use, information on the control system design and control parameter settings is required. It is essential that a proper VFD closed pump system be designed which will increase energy savings, enhance control performance and improve system operations. In this article we will discuss typical methods of flow control by industrial fans and power which are very dominant in industrial application and in the field of Industrial automation and control. Fans, blowers and pumps constitute a large application of motors. In such application how flow is to be controlled by driving a pump. If driving a pump by a motor it will extract certain amount of air. Demand of air and water is not same at all time. It depends upon pump characteristics and machine characteristics that is how operating point is determined. Flow is to be varied by varying the operating point. The most common characteristics we will demonstrate the energy saving with variable speed drive method of flow control. Variable speed drive method is the most vital technology in industrial and automation control. On Off control method is not used in industrial process.Because in on off control method there is pulsating flow.

$$\text{Average flow rate} = Q_{\max} \times t_{\text{on}} / (t_{\text{on}} + t_{\text{off}})$$

In industrial processes the air fuel ratio should be perfect that is full combustion of fuel. Pulsating value of flow is not good for combustion. Similarly for industrial cooling processes the on off control method is not appropriate. When discussing energy savings and variable frequency drives (VFD) the attention often focuses on a centrifugal fan or pump application. However, you should not overlook other applications which also have large potential energy savings and energy recovery.

Centrifugal Applications

When a centrifugal fan or pump is used with mechanical flow control, converting the application to an adjustable speed AC drive can reduce energy costs by 10%–55% if the fan or pump is designed to operate between 40% and 75% of full speed. This usually provides a return on investment which is in the 6–20 month time frame. The Laws of Affinity, which shows an operating range that produces the most flow or pressure per horsepower. The increasing potential benefit from VFD can be estimated from the table below. This is particularly important as "When considering total cost of ownership for an industrial electric motor system, 95%–99% cost is expended on motor energy requirements" (Hart, 2012).

Table 5 shows Estimation of Electrical Energy saving potential through speed control with ratio of actual to full load quantities and percentage reduction in power saving potential. In real life, say in case of one of the leading iron and steel industry in India, the motor loading is generally lower than 80%, as shown in **Table 7**, and so the energy saving potential is up to 49%. When comparing the different methods of mechanical flow control it is clear to see only a VFD gets close to the maximum efficiency of the theoretical fan curve or Pump Flow.

Case Study of India

Table 6 gives sector wise contribution to India GHG emission profile (MEFCC, 2018, 2015; Liu, 2018; Carbon trust, 2018). Energy contributes to as much as 71% of India's carbon emissions and share is shown to be increasing. Therefore, the Government of India has taken up National Action Plans on Climate Change to meet the Sustainable Development Goals of the United Nations. Energy tops the list with first two missions are aiming to enhance use of renewable energy and energy efficiency, all to reduce the carbon emission intensity as India is a signatory to UNFCCC and committed to achieve the set goals.

National Action Plan on Climate Change: Eight National Missions

- (1) Jawaharlal Nehru National Solar Mission.
- (2) National Mission for Enhance Energy Efficiency.
- (3) National Mission on Sustainable Habitat.
- (4) National Water Mission.
- (5) National Mission for Sustaining the Himalayan Ecosystem.
- (6) National Mission for a Green India.
- (7) National Mission for Sustainable Agriculture.
- (8) National Mission for Strategic Knowledge for Climate Change.

Table 5 Estimation of electrical energy saving potential through speed control

Sr. no.	Ratio of actual to full load quantities				% reduction in power saving potential
	Speed	Volume flow rate	Pressure head	Input power	
1	1	1	1	1	0%
2	0.9	0.9	0.81	0.729	27%
3	0.8	0.8	0.64	0.512	49%
4	0.7	0.7	0.49	0.343	66%
5	0.6	0.6	0.36	0.216	78%
6	0.5	0.5	0.25	0.125	88%
7	0.4	0.4	0.16	0.064	94%
8	0.3	0.3	0.09	0.027	97%
9	0.2	0.2	0.04	0.008	99%

LOAD	CO ₂ Emission(t/h) for 10,000 HP motor		
	Without VFD	With VFD	CO ₂ emission saving
100%	47,747	45,928	1819 (3.809%)
80%	37,287	26,829	10,458 (28.048%)
50%	28,648	9094	19,554 (68.254%)

Iron and Steel Industry in India ranks second after power industry in terms of energy use and hence emission of carbon and therefore the Government of India has Designated Consumer with very high target to reduce specific energy consumption and hence emission through an innovative mechanism called Perform Achieve and Trade (PAT). A large number of energy audits has been conducted and huge savings have been achieved through implementation of the recommendations of such studies. In Summary, a few examples of case studies at JSW Works (erstwhile ISPAT Industries Ltd), at Dolvi and Kalmeshwar, Maharashtra, India (based on Energy Audit conducted by IISWBM, Kolkata, India), are placed below:

Table 7 highlights Energy conservation opportunities for Iron and steel Industry for Ispat India Ltd at Dolvi Mumbai. It may be noted that in most of the cases where VFD has been found to be techno-economically viable, the opportunities are favourable over time as the cost of electricity has been increasing at much higher rate than the cost of equipment. In some cases, the cost of VFD has practically come down. Thus, in all the four cases taken from a leading industry unit of 5 TPA capacity of steel production in India have simple payback period less than half-an-year and Return on Investment (RoI) more than 160% per annum. Use of VFD has found its significance even in India's First Biennial Update Report to the United Nations Framework Convention on Climate Change (MEFCC, 2015) where in another leading Industry house, for example, 'Balmer Lawrie & Company (BL)', pointed out the savings achieved through VFD.

Carbon dioxide (CO₂) generated as the consequence of electrically driven industrial machines contributes to global warming. In an effort to reduce CO₂ emissions from industry, this article focus on industrial electric motors equipped with variable frequency drives as the resources of reducing CO₂ emissions. Many machines such as pumps, fans or compressors used in an industrial applications, no matter if they are big or small, are driven by electric drives. Thus, improving the efficiency and saving the energy use of electricity as well as reducing the CO₂ emissions generated by the use of these motors are paramount factor in improving industrial usage. The intensity of CO₂ Emission Savings with for 10,000 HP motors, are shown in **Tables 8** and **9** (see "Relevant Websites section").

The above result shows significant CO₂ Emission reduction with VFD. Applying VFD decrease the emissions of carbon dioxide for use of fans. When the load is half, the savings are significant in comparison with 100% load.

Conclusion

Carbon footprint of industry is one of the vital issue in mitigating the impact of global warming. Industry accounts for more than 40% of world electricity consumptions and out of which more than half is due to electrical motors. From the above evidences it is clearly visible that applying variable frequency drives does decrease CO₂ emission significantly besides increasing energy efficiency. In this article overview of different case study of industrial sector as per USA and Indian perspective are analyzed with respect to carbon footprint and its environmental implications. In India Iron and steel Industry is considered to be designated consumer with synergy to reduce specific energy consumption and hence CO₂ emission through harbinger of technology known as Performance Achievement and Trade (PAT) scheme with respect to carbon dioxide emissions and its synergy of minimization is discussed. Article give in depth study related to harmonics and system efficiency for variable Frequency Drives. Environmental degradation due to carbon footprints are to mitigate and previous data are interpolated for future research. Latest trends and technology as per Indian perspective are of broad area of research for carbon footprints and it can be mitigated by technical awareness and up gradation of technology. Thus applying variable frequency drives are not only to improve the efficiency of motor driven equipments to control load and flow but also significantly reduce carbon footprint.

The Impact of Variable Speed Drives on the Carbon Footprint of Electric Motors Used in Industry.

Is the Production of Biofuels Environmentally Sustainable?

Lucas Reijnders, University of Amsterdam, Amsterdam, the Netherlands

© 2020 Elsevier Inc. All rights reserved.

Introduction (Zinoviev *et al.*, 2010; Reijnders, 2018, 2019)

This article deals with the production of biofuels. Biofuels are renewable. They are based on recently generated biomass. This contrasts fossil fuels which are based on very old, converted biomass. The focus here is on modern biofuels, biofuels which are applied using advanced conversion technologies. Current commercial modern biofuels include gasified biomass and wood pellets applied in advanced power generators and biogas produced by anaerobic conversion and applied in advanced combustion (whether or not after purification). Liquid biofuels applied in modern cars are also included. Modern biofuels are mainly generated on the basis of plant-derived biomass. They can be made from terrestrial lignocellulosic biomass (e.g., woody biomass or harvest residues), from algae, from non-edible oils derived from terrestrial plants, or from terrestrial food (including feed) crops, such as sugarcane, corn, oil palm, rapeseed and wheat.

Use of biomass for electricity generation is currently mainly based on forestry. Cultivation of fast growing plants (e.g., willow) and harvest residues from agriculture (e.g., straw) can also be a source of biomass for power generation. Production of liquid biofuels from substances generated by terrestrial plants that can also be sources of foodstuffs, such as starch, sugar and oil, predominates so far the production of modern liquid biofuels. Currently, about 5% of worldwide food (including feed) production serves the generation of liquid biofuels. Biogas production is based on a wide variety of substrates, including excrements, production residues and crops. Biofuels based on the cultivation of microalgae are under development but as yet not commercially produced. Biofuels that are under discussion include liquid biofuels produced by thermochemical treatment of biomass and bio-hydrogen. There are ambitious plans for the expansion of modern biofuel production.

In this article the question will be raised whether modern biofuels are environmentally sustainable. Environmental regards here: Natural resources, living nature and pollution. Sustainability is a concept which has many operational definitions. Here environmental sustainability will be defined in terms of nearly no decrease of natural capital and resources derived from natural capital that are to be transferred to future (human) generations. *Ceteris paribus*, this would allow for the near indefinite availability of current natural capital and resources derived thereof. Natural capital is defined as the stock of natural assets providing, or able to provide, services to mankind. Such services include the provision with natural resources such as clean fresh water, ores and fossil fuels. Also included are: soil fertility, environments conducive to health, the pollination of crops and climate regulation. The requirement that natural capital and resources derived thereof should not decrease is in line with early definitions of sustainability and with justice between generations. Constancy of natural capital and resources derived thereof fit a steady state economy, an economy in equilibrium with its environment. The qualification 'nearly' in 'nearly no decrease of natural capital and resources derived thereof' is linked to the usage of natural resources which are generated by slow geological processes, such as ores and fossil fuels. No decrease of natural capital would imply that only the ongoing addition to stocks of such resources could be consumed. In the case of many human generations, justice between the generations, however, would allow for limited consumption of natural capital and resources derived thereof beyond the current addition to stocks of natural resources generated in slow geological processes.

A focus on natural capital does not mean that social and economic matters are not important for sustainable development. On the contrary, such matters are highly relevant, also in the context of modern biofuels. The emergence of modern biofuels is linked to socio-economic considerations regarding energy security and farmer's income. Indirect land use change following from the use of food crops for biofuel production due to the economic inelasticity of the demand for food is an important impact of modern liquid biofuel production. Another important impact concerns the displacement of people with insecure land rights by large scale plantations used for modern biofuel production and the effects of using marginal soils for producing biofuels on people currently using such marginal soils for their livelihood. However, there is a case for considering the conservation of natural capital and resources derived thereof as a pre-condition for sustainable development.

Natural capital has many components, reflecting in part the diversity of environmental factors and of natural resources on which an economy depends. In this article a selection of contributions to natural capital will be discussed, based on their relevance to biofuel production. They are important for the production of biofuels and/or substantially affected by the production of biofuels. The contributions to natural capital that will be discussed here are:

- Clean fresh water,
- Soil and soil organic carbon,
- Plant nutrients,
- Living nature providing ecosystem services,
- Fossil fuels,
- Climate as affected by the emission of greenhouse gases and other atmospheric impacts of biofuel production.

These contributions to natural capital will be considered in the following sections.

Clean Fresh Water (Reijnders, 2014a,b; Filoso *et al.*, 2015; Reijnders, 2019)

If compared, per unit of energy produced, with fossil fuels, with solar energy and wind energy, biofuels based on terrestrial crops are characterized by a relatively large consumption of fresh water (surface water, ground water and precipitation such as rainwater). Per unit of energy produced, the fresh water consumption linked to biofuel production from terrestrial crops can be a factor 10^3 – 10^4 larger than the fresh water consumption linked to production of fossil fuels, of solar energy and wind energy. Water consumption per unit of energy produced linked to forestry-based and algal biofuel production is also much larger than the fresh water consumption linked to production of fossil fuels, of solar energy and wind energy. A large consumption of fresh water is problematic when there is fresh water stress (not sufficient sustainably available water to meet demand). Worldwide fresh water stress is increasing. It is estimated that fresh water stress will affect about two-thirds of mankind by the year 2025. Water stress is closely bound up with food production, climate change and population pressure. In practice reversal thereof is very hard, which suggests that current water stress is important to the inter-generational transfer of natural capital linked to fresh water. Ecosystem services (see Section “Living Nature Providing Ecosystem Services” (Reijnders and Huijbregts, 2009; Curran *et al.*, 2014; Reijnders, 2014a; Verdade *et al.*, 2015; Gasparatos *et al.*, 2018)) can be negatively affected by exacerbating fresh water stress.

In practice biofuel production has contributed to increased fresh water stress. An increase in biofuel production may further exacerbate fresh water stress. There is, however, scope for improving water efficiency in biofuel production. Improved water efficiency can reduce water consumption, but it would seem widely beyond the scope of technology to reduce fresh water consumption per unit of energy produced to levels in the order of fresh water consumption linked to the production of fossil fuels, of wind energy and solar energy.

Apart from water pollution linked to erosion, which will be considered in the next section, the cultivation of terrestrial biofuel crops may lead to the pollution of surface and ground water by added plant nutrients (fertilizers) and pesticides. When such substances are persistent (for instance in groundwater and sediments) natural capital to be transferred to future generations may be negatively affected. For instance, in Brazil elevated concentrations of heavy metals such as Cd have been found in aquatic organisms and sediments affected by sugarcane cultivation. This is presumably caused by the presence of heavy metals in added plant nutrients. Such heavy metals may have a longstanding negative impact on natural capital. Their removal from fertilizers before application is preferable.

High inputs of plant nutrients tend to be conducive to large biomass yields, and these are often preferred by cultivators. Pesticide use tend to be larger for food (including feed) crops than for lignocellulosic crops, but it is not certain whether this difference will persist when lignocellulosic crops are further domesticated. Persistent nitrate and pesticide concentrations in groundwater used for the production of drinking water resulting from intensive crop cultivation may exceed standards safeguarding human health. The concentration of phosphorus- and nitrogen- based nutrients in surface water affected by the cultivation of biofuel crops may negatively affect water ecosystem quality and may be conducive to blooms of cyanobacteria which can be a nuisance and may be detrimental to human health. Eutrophication of water systems, including persistent elevated concentrations of plant nutrients in sediments, may have longstanding negative effects on biodiversity in ecosystems and thereby on natural capital.

Conversion of biomass into liquid biofuels can be linked to the generation of waste water containing large amounts of organic substances and plant nutrients. Treatment options exist which can sharply reduce waste water concentrations of plant nutrients and organic substances, but when these are not used, surface water quality may be seriously affected. This is well documented for the wet processing of fruit bunches of oil palm to generate palm oil. Insufficient treatment of palm oil mill waste water is linked to large negative impacts of mill effluents on surface waters. In the case of Brazilian sugarcane processing to ethanol, large volumes of watery vinasse, containing organic substances and plant nutrients, are generated as by-product. In Brazil vinasse tends to be applied to sugarcane fields. This may e.g., lead to excessive K concentrations in groundwater, in which K may persist for a long time, and in surface water.

In the case of biofuels from cultivated fresh water algae, much depends on the recycling of water used for algal cultivation. Such recycling may well be partial in view of preventing the accumulation of substances and pests which can negatively affect subsequent production of freshwater algae. The environmental burden of algal biofuel production for water will be dependent on the treatment of non-recycled water.

Both increased fresh water stress and persistent water pollution can be considered a reduction of natural capital. This does not mean that there can be presently no biofuels, without a negative effect on fresh water related natural capital. A case in point regards biofuels based on forestry with no or very low inputs of plant nutrients and pesticides in areas which are not subject to fresh water stress.

Soil and Soil Organic Carbon (Blanco-Canqui and Lal, 2009; Reijnders, 2014a; Filoso *et al.*, 2015; Lal, 2018)

Erosion of soils under cultivation as arable land may exceed erosion in natural ecosystems by one to two orders of magnitude. Soils of sloping arable land are more at risk of erosion than horizontal soils. *Ceteris paribus*, soils under multiannual cover of crops are less prone to erosion than those under annual crops. Harvesting operations in forestry may also cause increased erosion.

Both wind and water erosion may be caused by biofuel feedstock production. Compaction of soils linked to the use of heavy machinery in biofuel production is conducive to increased water erosion. After deposition from air or water part of eroded soil may contribute to the future production of biomass, but a net loss of productive soil, which is loss of natural capital, is very likely. Sustainable use of mineral soils would require that the net loss of productive soil due to erosion does not exceed productive

mineral soil formation due to natural processes such as weathering. Current biofuel feedstock cropping practices often do not meet this requirement.

Much can be done to limit erosion. In the case of cultivation on arable land, reduced tillage, cover crops, addition of harvest residues, windbreaks to reduce wind erosion and traps for water-eroded soil such as vegetation buffers may contribute to reduced soil losses due to erosion. Selective harvesting in forestry may cause a lower loss of natural capital due to erosion than clear cutting.

Soil organic carbon is of major importance in the limitation of erosion. Also soil organic carbon contributes to water conservation, soil productivity, soil biodiversity, nutrient supply and the reduction of nutrient emissions. The net emission of carbonaceous greenhouse gases from soils is dependent on changes in soil organic carbon stocks. Thus, maintaining levels of soil organic carbon in productive soils and restoring soil organic carbon in depleted soils is relevant to natural capital. Environmental sustainability requires that soil organic matter stocks should not decrease in quality or quantity.

Relatively productive crops, reduced tillage, cover crops and the addition of harvest residues, manure and compost to soils are conducive to the maintenance and restoration of soil organic carbon. The removal of harvest residues for biofuel production may be detrimental to soil organic carbon stocks in mineral soils. Whether this indeed occurs depends on cultivation practices. In the case of reduced tillage, highly productive crops, the use of continuous crop cover, and the addition of manure and compost there may be scope for removal of harvest residues without compromising soil organic carbon stocks. Cultivating bioenergy feedstocks on peat is usually unsustainable because of the net loss of soil organic matter due to cultivation practices such as drainage.

Current cultivation practices may lead to accumulation of heavy metals in soils. The uses of plant nutrients present in sewage sludges, combustion ashes, synthetic P fertilizer (in which substantial amounts of cadmium and uranium may be present) and swine manure (which may contain elevated levels of Cu) have been noted to contribute accumulation of heavy metals that may have a longstanding negative impact on natural capital linked to soil quality. Selective use of sources of plant nutrients on the basis of low bioavailable heavy metal concentrations and better purification in the processing of phosphate ores to synthetic fertilizer are obvious antidotes against accumulation of heavy metals in soils.

Plant Nutrients (Reijnders and Huijbregts, 2009; Reijnders, 2014a,b, 2019)

The indefinite availability of adequate amounts of plant nutrients, such as Ca, Cu, K, Mg, N, P, S and Zn, is important for the environmentally sustainable production of biofuels. Natural processes such as weathering and N-fixation provide addition to nutrient stocks in soils. When biomass is harvested from production systems fed by natural processes, withdrawal of nutrients may exceed natural additions to stocks, leading to decreasing stocks over periods of time relevant to generating new biomass from the same soils. These decreases may be counteracted by recycling nutrients associated with biofuel production to new biomass production. Such recycling practice is, however, rare. Also, in practice such recycling is not without problems. Ashes originating in biomass combustion may show deficiencies in N and S and may induce increased leaching of N-compounds and inhibit plant growth. Cd may accumulate in soils due to the recycling of biomass combustion ashes. For such reasons addition of biomass combustion ashes to soils is restricted or prohibited in several European countries.

Biomass production in systems which are only fed by natural processes is often considered too low for profitable exploitation. This in turn leads to inputs of fertilizers to achieve elevated levels of nutrients such as K, N and P. As noted in Section "Soil and Soil Organic Carbon" (Blanco-Canqui and Lal, 2009; Reijnders, 2014a; Filoso *et al.*, 2015; Lal, 2018), use of those fertilizers may lead to concentrations of substances in soils that have negative impacts. Large inputs of fertilizers may also be associated with relatively high losses of plant nutrients from biomass production systems. These losses may be partly counteracted by cultivation practices conducive to soil- and soil carbon conservation and by the use of deep-rooting plants.

In practice, the production of modern biofuels often tends to be characterized by substantial to high losses of plant nutrients. It might be argued that such losses of natural capital are not a major problem for plant nutrients such as Ca, K and Mg as these nutrients are geochemically abundant. N is abundant in the atmosphere and synthetic N fixation may be powered by wind and solar energy which are characterized by practically indefinite availability. However, plant nutrients such as Cu, P and Zn are not geochemically abundant. For instance, much of P used in biofuel feedstock production is currently provided from ore stocks that have been generated in slow geological processes and are in practice limited. It has been estimated that when mankind runs out of such stocks, natural processes combined with a 90% efficiency of recycling of P in harvested biomass can only supply 3.10^9 people with food. It has been argued that in view thereof the use of ore-derived P should presently only serve its essential use in food production. All in all, the current use of plant nutrients for biofuel feedstock production negatively affects natural capital to be transferred to future generations.

Living Nature Providing Ecosystem Services (Reijnders and Huijbregts, 2009; Curran *et al.*, 2014; Reijnders, 2014a; Verdade *et al.*, 2015; Gasparatos *et al.*, 2018)

Living nature provides mankind with a variety of ecosystem services. These include the provision of food and wood, cleansing of air and water, the provision of pest predators, pollination, ecotourism, climate regulation, protection against 'dustbowls' caused by wind erosion and against natural hazards. Ecosystem services provided by nature are linked to biodiversity: The diversity of species in natural ecosystems. The relation between ecosystem services and biodiversity may be non-linear, e.g., due to the presence of

keystone species, that have a relatively large impact on ecosystem services. The impact of biofuel production on ecosystem services provided by nature is dependent on the nature of the biomass involved, land use and production practices.

Replacement of living nature by food (including feed) crops for biofuel production has occurred on a substantial scale. Examples are the replacement of biodiverse Cerrado natural ecosystems by sugarcane production in Brazil, the replacement of miombo woodland in sub-Saharan Africa for sugarcane production and the replacement of tropical forest by oil palm plantations in South East Asia. In these replacements biodiversity has been substantially reduced.

In the case of cultivating lignocellulosic feedstocks the reduction of biodiversity may be less than in the case of conventional food and feed crops. The presence of buffer zones adjacent to biomass-for-biofuel cultivation may mitigate the reduction of biodiversity.

The inelasticity of demand for food implies that replacement of living nature may also be indirect. In this case diverting food crops on existing agricultural land to biofuel production leads to extra cultivation for food elsewhere, where living nature may be replaced.

Fallow and abandoned land has also been used for the expansion of modern biofuel production and there has been advocacy for more extensive use of fallow and abandoned land to produce biofuel feedstocks. When agricultural land becomes fallow or abandoned, living nature can make inroads, leading to increases in biodiversity. Such increases are, however, not general. A case in point is provided by *Cylindrica imperata* grasslands that cover parts of abandoned agricultural land in the tropics but show little biodiversity. However, often biodiversity is much increased after long periods of fallow or abandonment. When biodiverse fallow or abandoned lands are taken into production to generate biofuel feedstock, biodiversity may be much decreased, with a negative impact on ecosystem services.

Biodiversity of living nature may be negatively affected by additional water consumption related to terrestrial biofuel production in areas subject to water stress. Emissions of plant nutrients, pesticides and organic substances linked to biofuel production may also negatively affect biodiversity of natural ecosystems. Sometimes such negative impacts may occur far away from their source. An example is the increased loading of the Mississippi river with nutrients originating in terrestrial crop production for biofuels, which leads to increased hypoxia in the Gulf of Mexico. In view of the impacts caused by added inputs of nutrients, pesticides and water, which often characterize intensification of cropping, it is uncertain whether such intensification, leading to higher yields per hectare and thus to reduced land use per unit of energy produced, will benefit ecosystem services provided by living nature.

The production of fresh water-based microalgal biofuels may negatively affect ecosystem services by land use change, impact on fresh water availability and waste water emissions. The use of forestry residues for biofuel production is likely to negatively affect animals, plants and fungi which are dependent on the presence of dead wood in forests.

It would seem that the expansion of modern biofuel production so far has had a substantial negative effect on biodiversity and ecosystem services provided by living nature. Reversal thereof tends to take long time spans (more than one human generation) and may well be incomplete. Thus, a negative effect of current biofuel production on natural capital to be transferred to future generations is likely.

The impact of non-fossil energy supply on ecosystem services provided by living nature may be much reduced by replacing bioenergy by other types of energy supply. The net energy production from a hectare of solar cells in the tropics exceeds the net energy generation of biofuels based on oil palm and sugarcane by roughly a factor 40–80. For wind energy the land requirement tends to be even lower than for solar cells. Though both wind and solar energy may negatively affect ecosystem services, their impact per unit of net energy produced is likely to be much lower than the negative impact associated with terrestrial biofuels.

Fossil Fuels (Reijnders and Huijbregts, 2009; Reijnders, 2014a, 2019)

Fossil fuels currently dominate worldwide energy supply, so it will come as no surprise that there are currently fossil fuel inputs in biofuel production. Fossil fuels are generated in slow geological processes. Their formation is ongoing but the addition to stocks is very small, if compared with worldwide fossil fuel consumption.

Fossil fuel inputs in biofuel production are currently e.g., linked to the input of synthetic fertilizers, the use of machinery in harvesting and transport and can also be substantial in biomass processing. Ratios of energy embodied in fossil fuel inputs to biofuel energy outputs can vary strongly: from relatively low for harvested wood to relatively large for European rapeseed-based biodiesel and US corn-ethanol. As current worldwide fossil fuel consumption massively exceeds the additions to stocks, the consumption of fossil fuels in biofuel production adds to the reduction of natural capital. Fossil fuel inputs can be much reduced and even eliminated by the replacement of fossil fuels as energy source by wind and solar energy. Fossil methane that serves as hydrogen donor in the synthesis of N-based fertilizers used in crop cultivation may be partly replaced by increased use of biological N-fixation and by hydrogen generated in solar- or wind power driven electrolysis of water.

Climate as Affected by Greenhouse Gases and Other Atmospheric Impacts of Biofuel Life Cycles (Reijnders, 2014a,b; Filoso *et al.*, 2015; Reijnders, 2019)

The consumption of fossil fuels discussed in Section “Fossil Fuels” (Reijnders and Huijbregts, 2009; Reijnders, 2014a, 2019) impacts climate, but is not the only impact of biofuel production on climate, as affected by greenhouse gases. Another impact of terrestrial biofuel production on climate is associated with changes in above-ground and soil carbon stocks, which in turn can

affect atmospheric CO₂ concentrations. Changes in soil carbon stocks in biofuel feedstock cultivation can be linked to tillage, to burning practices and to cultivation of crops on drained peat. Land use change directly linked to biofuel production can impact carbon stocks (e.g., in case of the replacement of tropical forests by oil palm plantations or the conversion of grasslands to plantations for the production of woody biomass). In the case of new oil palm plantations on peat which replace tropical rain forest, the life cycle CO₂ emission for palm oil-based biodiesel during the lifetime of the plantation is larger than the life cycle CO₂ emission for fossil diesel. Thus, biofuels do not necessarily mitigate the greenhouse effect or carbon footprint if compared with fossil fuels. Carbon stocks may decrease or increase due to direct land use change. An increase of aboveground carbon stocks can e.g., occur when grasslands are converted to plantations for woody biomass, whereas in the case of replacement of tropical forest by oil palm plantations the opposite occurs. Land use change can also be indirectly linked to biofuel production. In the latter case the use of food crops for biofuel production is associated with land use change elsewhere because the demand for food is inelastic. CO₂ is emitted when biofuel production residues and/or biofuels are burned. The latter emission is often valued at zero, because it is assumed to be compensated by sequestration of the same amount of CO₂ by new photosynthesis. However, in the real world new photosynthesis in part sequesters CO₂ that is emitted by the combustion of fossil fuels and due to land use change. Moreover, permanent sequestration of CO₂ emitted by biofuel combustion is not assured.

The emission of other greenhouse gases than CO₂ can also be linked to the production of biofuels. Crop-based biofuel production is associated with substantial emissions of the greenhouse gas N₂O. High inputs of N- and K-based nutrients can be conducive to high emissions of N₂O. In the case of biogas production from biomass, there can be substantial fugitive emissions of the greenhouse gas methane (CH₄).

When the emissions of CO₂, N₂O and CH₄ linked to biofuel life cycles are considered, it is often far from certain that claimed climate benefits of liquid biofuels and biogas, if compared with fossil fuels, do indeed occur.

All in all, biofuel production significantly contributes to the emission of greenhouse gases. As the effect of increased atmospheric concentrations of these greenhouse gases, which is predominantly negative, persists for a long time, this negatively affects natural capital to be transferred to future generations.

Significant negative impacts of biofuel production on air quality may follow from burning practices associated with feedstock cultivation. Such practices have been well documented in case of Brazilian sugarcane cultivation (where they show a diminishing trend). Exposures negatively affecting human health associated with such burning practices have been noted. Particulates and polycyclic aromatic hydrocarbons (PAH) have been implicated in negative impacts of burning practices to human health. As PAH tend to be poorly degradable and may retain bioavailability, there may be a longstanding negative impact of burning practices on natural capital. Another type of emission associated with biofuel production which may have long lasting negative effects on natural capital is the emission of volatile N-compounds that may lead to acidification and eutrophication.

Conclusion

It emerges from the previous sections that current biofuel production is often at variance with the conservation of natural capital that is to be transferred to future generations. In part this is linked to the 'background' of the present state of the world, as related to other human activities. The fresh water consumption associated with biofuels would probably not be a problem in the absence of widespread man-made fresh water stress. The use of fossil fuels in biofuel production is linked to the current dominance of fossil fuels in the world economy. Large scale use of phosphate ores is strongly connected to feeding the present large world population. Thus the answer to the question 'are biofuels environmentally sustainable?' can be highly context-dependent. On the other hand, there is not always strong context-dependency of environmental sustainability of biofuel production. Burning practices in sugarcane production are far from general. Both dry processes and efficient waste water treatment are practiced in parts of palm oil production, and this matters for water pollution. Plant nutrients can be purified before addition to biofuel feedstock cultivation and this can prevent accumulation of heavy metals in soils. Commercial agricultural systems managed in ways that prevent reduction of soil organic carbon stocks are operational. Also the context of biofuel production can change, with benefits to the conservation of natural capital. Fossil fuels may, for instance, be replaced by solar and wind energy systems (in which geochemically scarce elements are subjected to highly efficient recycling).

In conclusion: Presently the answer to the question whether current modern biofuels are environmentally sustainable should often be: No. However, there are options available to make biofuels less environmentally unsustainable.

Introduction

United Nation Framework Convention for Climate Change's (UNFCCC) latest Climate Change Conferences (Conference of Parties) – COP24 as well as international climate change agreements are aimed to meet ultimate target of low-carbon economy and tackle global warming to achieve goal of sustainable development. After COP24, the new international regulation suggested that all countries should report their emission cutting progress every two years from 2014 (Carbon Brief, 2018).

The increasing concentrations of carbon dioxide (CO₂) is a serious threat to the earth's environment and to tackle number of new concepts and policies like “carbon footprint”, “low-carbon economy”, “low carbon technology”, “low carbon development”, “a low-carbon lifestyle”, “low carbon city” are coming but unfortunately low carbon became a fashion than real actions. Scientific modeling of climate change suggested that if the growth in global temperatures held below two degrees, there is some hope that negative outcomes of global warming can be avoided (IPCC, 2007). An essential part of climate change mitigation involves replacing fossil fuel-based energy production systems with low or zero-carbon energy sources (Snell and Schmitt, 2012).

The low carbon economy defined as ‘the activities which generate products or services which deliver low carbon outputs’ (DBIS, 2015). The European Commission (2016) has a roadmap which states that by 2050, the EU should reduce emissions to 80% below 1990 levels. The Paris Agreement establishes a new mechanism for post-2020 global climate governance and sets long-term goals to accelerate worldwide low-carbon transformation of economic development, promote the revolutionary reform of energy system which helps to develop industrial civilization to eco-civilization (He, 2016). To date, very few countries have demonstrated the willingness or capacity to make these necessary changes.

Based on the recent development of low carbon economy, this article highlighted the existing problems of low-carbon economy in developing countries and some alternatives to overcome the problem including the energy efficiency, technology modification and country level carbon financial system and suggestions to achieve at country level.

Low Carbon Economy Status – Worldwide

The IPCC's Fifth Assessment Report (IPCC, 2014) confirmed that the impacts of climate change are increasing, largely driven by anthropogenic Greenhouse Gas (GHG) emissions. New innovations along with demand-focused policies favouring low-carbon economy are vital for every country worldwide. To know what amount of attention a particular country must provide, it is required to know how much a particular country is contributing and to what extent the country is willing to engage to keep global temperature below 1.5°C. Historically developing countries contributing less to GHG emission than developed countries. They need to concentrate more in carbon-intensive investment with the aim to reduce poverty. For example, countries in East and South Asia and the Pacific which have reduced their levels of poverty have in turn increased their emissions over 200%, while regions like Sub-Saharan Africa (which have experienced increases in poverty) have in turn had decreases in carbon emissions (Goldstein, 2015). Research shows that while urbanization in developing countries is decoupled from industrialization, suggesting a different trajectory for increases in carbon emissions (Vollrath et al., 2016). Developing countries are more energy intensive than developed countries (Fankhauser and Jotzo, 2018). Therefore the role of developing countries is very much essential to limit global temperature increase.

Low Carbon Development and Developing Country

Stabilizing the world's climate change and successfully addressing Sustainable Development Goals (SDGs) would not be possible without effective planning and implementation of low carbon economy by developing countries. The effective policy to address

three dimensions of sustainability with an integrated model and a realistic approach is the solution to make it effective within 2030. According to [Steckel et al. \(2017\)](#), the main challenge is to avoid future emission in different energy consuming sectors through emission-intensive technologies. Though policy instrument like 'carbon prices' was often rejected by developing nations, new comparative sustainable economic growth policy is required. [Jakob et al. \(2016\)](#) proposes use of revenues from carbon pricing to finance infrastructure investment. In many countries, the revenues which a government can collect from taxing CO₂, can then be utilized to finance measures for achieving the SDGs, e.g., access to water, sanitation or electricity. [Dorband \(2016\)](#) shows that a carbon tax applications turns out to be largely progressive and minimizing emission concerns. Many fast developing countries have developed targets for near future and to achieve low-carbon economy. **Table 1** presents comparative analysis of low carbon policy and development – China vis-a-vis India.

Innovation, Financing and Sub-National Actions

Along with policy initiative, new innovative practices in low-carbon technologies, financing, and actions are focus areas that will enable China and India to achieve their emission reduction goals (**Table 2**).

Low Carbon Green Growth in Asia

Clean renewable energy approach and low-carbon technology is widely viewed as the next step of development and economic growth. Most governments are aware of innovation and new technological growth. For example, the Government of Republic of Korea recognized offshore wind power as its next big global player ([GGGI, 2011](#)). Globally, various governments and businesses have adopted green and clean energy solutions with an aim to deduce carbon emission. The involvement of different sectors like power, manufacturing, energy, environment, transportation is vital to develop low-carbon economy in Indian scenario.

The ASEAN region which is usually known as a rich natural energy region in the world, some countries in ASEAN perform quite poorly with regard to energy resources. According to [The World Bank Database \(2016\)](#), 4 out of 10 countries in ASEAN are energy importing countries including Singapore (98%), the Philippines (46%), Thailand (42%) and Cambodia (33%). Other countries such as Brunei, Indonesia, Myanmar and Vietnam whose main source of income is commercial energy, will continue to provide important energy resources to other countries in the region.

Policy Framework for Low Carbon Economy

The policy framework of low-carbon economy is basically based on policy instruments that governments are using to meet the climate change mitigation targets.

Howes and Dobes (2011), had an analysis and the discussion was divided into two sections – technology based policies and carbon-pricing policies. Technology-based policies are in favor of a particular technology or a group of policies. On the other hand, carbon-policies are based on how emission reduction occurs to market forces, technology policies or research and development funding involve in favor of a particular technology or project. Both carbon pricing and technology policies are aimed to evaluate market failure in different ways. Table 3 detailed climate change policy instruments under these two categorization.

Low Carbon Development Strategy and Lifestyle Choices

Asia is the most populous continent accounting for 60% of the world population where the world's two most populated countries, China and India, together constitute about 36% of the world's population (World Population Review, 2018). Energy consumption was increased in most of Asian countries, such as China, India, Indonesia, Malaysia and South Korea. Chinese energy consumption rose twice as fast as in 2016, pulled-up by a strong industrial demand, energy efficiency gains in the industry and national policies to decarbonize the economy (Global Energy Statistics Year Book, 2018).

World's growth patterns have demonstrated that it is not necessary to consume excess energy in order to improve the Human Development Index (HDI) of the United Nations Development Programme (UNDP), which is used as a measuring level of development of a country. But along with the development, there is a trend to depend on more resources, products and so produce more waste. Along with technological development, it is now possible to find solutions that are decentralized, energy efficient, cost-effective and some of them are well-suited for developing nations.

Human Development Index (HDI) of any country is influenced by their per capita energy consumption. Fig. 1 present the status of energy consumption and HDI. Three important observations from the Fig. 1 emphasize the need to focus on India and China as developing nations:

- (1) Improvement in Human Development Index (HDI) calls for higher per capita electricity consumption
- (2) After a certain level (say 4000 units/head/year) of electricity consumption, the HDI does not increase significantly and rather shows a diminishing rate of impact on HDI.

- (3) If India and China would follow the average path assuming to become developed economy at average electricity consumption rate of about 8000 kWh/head/year, another earth without population but full resources, besides our mother earth, would have been necessary for sustainable development. On the other hand, if India and China apply all learning worldwide to apply locally as per appropriate, in the process of becoming developed nation, it could be possible at around 2000 kWh/head/year. Hence our special attention in this article has been India and China, along with global issues.

Table 6 Potential of demand reduction from determined effort scenario to heroic effort scenario for India

Sectors	Sector demand in 2012 (TWh)	Demand in 2047 (TWh)			Policy response
		Determined effort	Heroic effort	% Savings	
Buildings	238	2287	1540	33%	Energy Conservation Building Code 2017 version is more versatile and optimistic with compared to the first version released in 2007
Industry	2370	10,430	6912	34%	Energy Conservation Act 2001 amended in 2010 is much more stringent than the first version. The Perform Achieve and Trade (PAT) mechanism applicable to 866 Designated Consumers Industrial Units in 13 sectors including larger commercial buildings. DCs consume more than 50% of India's Energy Consumption
Transport	929	4414	2975	33%	Green Mobility Mission: by the year 2030, 100% of the vehicles will run on electricity, later reduced to 50%
Pumps and Tractors	237	798	533	33%	Large utility in Agricultural Sector feeding the large is fast undergoing mechanization
Telecom	83	184	66	64%	Highest % saving opportunity in this high growth sector
Cooking	1072	522	410	21%	A consistent improvement is in place because of increasing awareness and government policy to shift to more cleaner safer and efficient mode of cooking, which was earlier based on direct burning of fire-wood in rural sector where almost 70% population lived
Total	4929	18,635	12,436	33%

Fig. 2 presents the global scenario gross domestic product – purchasing power parity and carbon dioxide emission.

This section attempts to highlight some policies development recommendations to improve awareness and decision making of people to change their lifestyle and help to minimize climate change.

Power Sector

Global electricity production and consumption are not sustainable. The main source of energy are fossil fuels such as coal, oil and gas which are the fastest growing contributor of carbon di-oxide contributor (**Fig. 3**). As of 2015, power generation in India accounted for 44% of domestic GHG emissions (**Ministry of Environment, Forest and Climate Change, 2015**).

Organizational standardized approach to account their GHG emissions and carbon footprint are implementing in many ways. Renewable energy certificates (RECs) which is used to manage indirect emissions and offsets which is used to reduce direct global emissions few approaches which are used to track and substantiate emissions reductions. The carbon footprint study is the basis of any low-carbon research and has been utilized by organizations to measure their product's carbon and take proper measures to reduce carbon emission and meet sustainable development goals.

Transport and Mobility

Transport is the key component of today's economic development and along with e-commerce the volume and intensity increasing around the world. The problems and challenges associated with transport are growing large amount of air pollution,

Fig. 4 Global GHG emissions under different scenarios and emissions gap in 2030. *Source:* The Emissions Gap Report 2017, UNEP, November 2017.

GHG emissions, petroleum dependency, traffic congestion, infrastructure cost and packaging waste. These are rapidly growing in developing countries where economic development and population is also growing rapidly.

It was mentioned in the document of Government of the Republic of India and the Government of the People's Republic of China in a Joint Statement on Climate Change between India and China that "climate change and its adverse effects are the common concern of mankind and one of the greatest global challenges of the 21st century, which needs to be addressed through international cooperation in the context of sustainable development". China and India reiterated that their bilateral partnership on the issue of climate change is mutually beneficial as well as globally significant (Kedia and Jain, 2015).

Table 8 Low carbon financial mechanisms in India

<i>Description</i>	<i>Type</i>	<i>Mechanisms in India</i>
Public finance and fiscal instruments	Tax revenue	Coal cess
	Coal cess Budgetary allocations and fiscal transfers	Annual budgetary allocations, center-state fiscal transfers
	Subsidies	Example include subsidies on solar heaters, electric vehicles, energy efficient appliances
Financing mechanisms	Fiscal instruments	Tax rebates
	Special Funds / Institutions	National Clean Energy Fund, state energy conservation fund, IREDA, sub-national funds
	Markets innovations	Indices such as Greenex and Carbonex
	Traditional market instruments	Green bonds for renewable energy, energy efficiency and green infrastructure projects
	Climate / energy market instruments	Clean Development Mechanism, Renewable Energy Certificates, Energy Saving Certificates
Risk management	Banking provisions	Special provisions for MSME, priority sector lending norms by the Reserve Bank of India
	Risk management mechanisms	The Partial Risk Guarantee Fund under the National Mission on Enhanced Energy Efficiency, Credit Guarantee Fund Trust for Micro and Small Enterprises
International sources	Grants	Bilateral and multilateral sources
	International climate finance	Green Climate Fund, Adaptation Fund

Source: Based on Kedia, S., Jain, N., 2015. Financing for Low Carbon Development in India (Policy Brief). Available at: http://www.teriin.org/projects/loci/pdf/res/Policy_Brief_LCD_Finance.pdf (accessed 21.01.19).

Waste Management

In the past, when the definition of waste was different that today, it was reused, transmuting into a new resource. This attitude of resource management still exists in villages in developing countries, where material cycle is completed, intimating the ecosystem. Every year we dump a massive 2.12 billion tons of waste and global waste to grow by 70% by 2050 unless urgent action is taken (The World Bank Report, 2018).

Low-Carbon Green Growth in Asia

Low-carbon green growth is provided recently whether in developed country or in developing country. But the different is quite similar with a large-scale industry and a small-scale industry. With changes there are many lifestyle change factors which are applicable in different levels (Tables 4 and 5).

Low Carbon Economy – Indian Perspectives

Sustainable Low Carbon Strategies in India

A relevant observation on opportunities while meeting the fundamental needs of people of India is placed below (Table 6).

Food: Harmonic development has been proved to be possible through growing number of successful organic farming. Bio-gas plant also produces green fertilizer besides providing energy from waste.

Cloths: The textile industry accounts for 14% of industrial production, which is 4% of gross domestic product employs 45 million people, and accounts for 13% of the country's total export basket.

Buildings: India's 2/3 of buildings yet to come up by 2030 to provide shelter then largest populous country. India can directly apply the latest advancement taken in this sector worldwide. Going green can reduce emission and help resource conservation by more than 50% in this sector.

Sustainability Challenges and Policy Response to Low Carbon Economy in India

Many natural species has become extinct for which they or their activities may not be responsible at all. Modern research also revealed that if this human civilization becomes extinct, it would be mainly due to anthropogenic intervention to nature. Supply side analysis of impact on Primary Energy Supply as a result of changes in demand pathways reveals the sustainability challenges in low carbon economy. The intervention cause, challenge and policy response are shown in the Table 7. Fig. 4 presents global GHG emissions under different scenarios and emissions gap in 2030.

Low Carbon Financial Mechanisms in India

Financial mechanisms for low carbon development in practice in India include public finance, traditional finance, risk management instruments, market-based tradable instruments, and international sources (Table 8). While there is no domestic carbon market

developed in India, instruments such as renewable energy certificates are traded at the Power Exchange India Limited. In terms of mechanisms developed by the central banking regulatory authority, there is a scope for the issuance of green credit guidelines.

Conclusion

It is revealed in this article that mitigation GHG emission and carbon footprint through Low Carbon Economy along with renewable energy approach is not an option but compulsion for sustainable development. The recent global economy growth also witnessed a considerable increase in global energy demand matched by overall increase in CO₂ emissions despite, some emissions have been prevented by switching from coal to gas that helped to avoid 60 million tonnes CO₂ emissions that would have come from coal. Additionally, a greater shift towards renewable energy in 2018 helped the world avoid 215 Mt in emissions. China and Europe led the global push for green energy. Increase efficiency of energy sources was the biggest saver in emissions, helping to avoid nearly 275 Mt in CO₂ emissions. An opportunity in the commercialization of low-carbon solutions, including energy efficiency and clean energy technologies, can support the transformation of the global energy sector. Simultaneously, this transition presents an enormous challenge given the significant capital required to transform economies that have been reliant on an energy system that has been largely fossil-fuel based. All the key objectives of MDGs are directly or indirectly related to low carbon economy, as it is one of the main drivers towards achievement of sustainability. The initiatives taken worldwide are worthy of praise but far from actual need, particularly in terms of practical actions. Some of the key findings to take this mission forward include awareness at all walks of life, inclusion in topics in syllabus from school level to all subjects of study in appropriately significant manner for strengthening awareness regarding implications of energy intensity and efficiency, innovative green technologies and techniques appropriate to the need, short-medium-and-long term policy and action plan in a P-D-C-A cycle to attain continual progress, as indicated in this article. To achieve the goal of low carbon economy for long term sustainability, the key potential areas has been found to be power, steel, cement and other industrial sectors including transportation and waste management, etc.

Manufacturing of Biodegradable Poly Lactic Acid (PLA): Green Alternatives to Petroleum Derived Plastics

Shubhalakshmi Sengupta, Suvendu Manna, Uttariya Roy, and Papita Das, Jadavpur University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Climate change mitigation and reduction in carbon footprint requires lowering of the emissions of greenhouse gases (GHG's). Petroleum based plastic production industrially in industries is responsible for GHG emissions and since they are non-biodegradable their incineration after use also contributes to the emissions. These growing environmental problems have led researchers to develop novel environment friendly materials from renewable resources which could be easily which will reduce emissions as well as be biodegraded after their use. The next generation of materials are now being developed keeping this environmental sustainability in mind. This has resulted in the development of biodegradable polymers which can replace the polymers from petrochemical sources effectively (An *et al.*, 2013). Polylactic acid (PLA) is one such polymer which can be used to produce environment friendly biodegradable materials for various industrial applications like automobile and electronics manufacturing owing to its enhanced mechanical properties (Huda *et al.*, 2008). PLA is a hydroxyacid derived polymer belonging to a family of aliphatic polyesters. The monomer lactic acid (2-hydroxy propionic acid) exist in optically active L- or D-enantiomers. The proportion of enantiomers results in the production of PLA with variable properties. Thus, PLA polymers can be produced in wide variety catering to various requirements of the materials produced. Since, PLA has good mechanical, optical and barrier properties in comparison with the commonly used petroleum based polymers it can be effectively used to replace them (Lim *et al.*, 2008).

Poly lactide (PLA) is one of the most promising biodegradable polymers owing to its mechanical property profile, thermoplastic processibility and biological properties, such as biocompatibility and biodegradability. Moreover, the degradation products of polylactides are nontoxic which enhances practical applications in biomedicine. PLA is currently being commercialized for a wide spectrum of applications. The polymer was first obtained by Carothers in 1932 as a low molecular weight product by heating lactic acid in vacuum. Although the initial work did not produce a high molecular weight polymer, DuPont was awarded a patent for a process to produce high molecular weight materials. The commercialization of the polymer for the bioabsorbable high strength suture VICRYL was taken up by Ethicon in 1972 (Avérous, 2008). This suture is a copolymer of glycolic acid and lactic acid in 90:10 ratio and undergoes relatively fast hydrolytic cleavage of the backbone ester linkage under alkaline or acidic conditions. is accelerated by in-situ formation of carboxyl end groups (Jamshidian *et al.*, 2010). This polymer in combination with other comonomers, such as caprolactone or glycolic acid, has produced interesting materials that could provide requisite behavior and performance as biomaterials (Gupta *et al.*, 2007).

PLA in comparison to other biopolymers has several advantages. These are: (1) The lactide monomer from lactic acid is obtained by fermentation from renewable resources, (2) The source i.e., corn's production results in fixation of carbon dioxide by the corn plant, (3) The manufacturing is energy saving, (4) It could be recycled back by alcoholysis or hydrolysis to lactic acid. (5) PLA could be used in manufacturing compostable hybrid paper-plastic packaging material, (6) Use of PLA materials in turn reduces landfill volumes, (7) it improves agricultural economy. (8) It could be used to make tailor made consumer products (Jamshidian *et al.*, 2010).

PLA has wide application in biomedical field due to its biocompatibility characteristics. PLA has been studied extensively for tissue engineering and drug delivery system and has been widely used in human medicine. Many of the PLA properties are compared to those polyethylene, polypropylene, polystyrene, and polyethylene terephthalate (such as stiffness, tensile strength, and gas permeability), turning PLA into a potential substitutes to petroleum based products such as trash bags, table utensils, films, paper coating, fiber, and cloth (Carlotta, 2001).

Poly lactic Acid (PLA)

Chemistry of Poly lactic Acid

The polymer PLA is processed by polymerizing lactic acid monomer. As discussed earlier lactic acid ($\text{HOCH}_2\text{CHCOOH}$) is a simple chiral molecule existing in two enantiomeric forms of D-lactic acid and L-lactic acid, differing in their effect on polarized light. The D and L isomer rotates the plane of light counter clockwise and clockwise respectively. D, L or meso form is racemic (equimolar) mixture of D and L isomers and is optically inactive. Lactic acid is produced in mammalian body is involved in Kreb's cycle through pyruvic acid and acetyl CoA synthesis and produced in muscles during glycogenolysis. Lactic acid is prepared by fermentation of molasses or dextrose of corn or potato starch. The structure of PLA is given in (Fig. 1).

Fig. 1 Structure of PLA.

Fig. 2 Schematic representation of petrochemical route of PLA synthesis. Reproduced from Gupta, B., Revagade, N., Hilborn, J., 2007. Poly (lactic acid) fiber: An overview. *Progress in Polymer Science* 32, 455–482.

Synthesis of Polylactic Acid

The basic building block of PLA is lactic acid. This can be produced by carbohydrate fermentation or by chemical synthesis. At present the majority of lactic acid production is done by the fermentation route. However different technologies have been developed to purify the products (Datta and Henry, 2006).

In the past another route of lactic acid production was prevalent upto 1990s where lactic acid monomer was produced from petrochemical feedstock. The produced lactic acid is an optically inactive racemic mixture of D and L enantiomers. Nowadays the more economic fermentation approach is used (Gupta *et al.*, 2007). A schematic representation is given below in (Fig. 2).

In recent years more usage of PLA could be attributed to the economical production of high molecular weight PLA polymers (100,000 Da). Several techniques have been adopted for their production which includes direct condensation polymerization, azeotropic dehydrative polymerization and/or polymerization through lactide formation. The commercially available PLA polymers are produced mainly by the lactide ring-opening polymerization route (Lim *et al.*, 2008).

Biosynthesis of PLA

Biosynthesis of PLA for commercial production utilizes corn as a feedstock. The corn first undergoes traditional milling in order to produce glucose/dextrose. Then glucose is fermented to form lactic acid. Many studies have been conducted to find other sources of carbohydrates for lactic acid production. The availability, purity and price of the carbohydrate feedstock determine its use. The agricultural by products used for lactic acid production include starch, cassava, lignocellulose/hemicellulose hydrolysates, Jerusalem artichokes, cotton seed hulls, beet molasses, cornstalks, sugarcane press mud, rye flour, wheat bran, barley starch, sweet sorghum, molasses, carrot processing waste, corn fiber hydrosylates and potato starch. Alternative sources of carbohydrate production includes fish meal wastes, Kitchen waste and paper sludge. Using kitchen wastes for PLA synthesis could help significantly in reducing domestic waste disposal problems in the cities. This will also reduce large amount of corn consumption (Jamshidian *et al.*, 2010; Carlotta, 2001).

The fermentation process for obtaining lactic acid for PLA synthesis is anaerobic. Anaerobic fermentations have more advantage over aerobic fermentation with respect to CO₂ balance. In industries homofermentive method is used more because of greater yields and small amount of byproduct generation (Jamshidian *et al.*, 2010). The bacteria lactobacillus is used in this process and the organisms commonly used are *L. leichmanii*, *L. amylophilus*, *L. bulgaricus*, *L. delbrueckii* at temperature range of 38–42°C and pH range of 5.4–6.4 with low oxygen concentration.

Fermentation is conducted in batch process commercially which takes about three to six days to complete. 5%–10% of sugar concentrations are used which produces about 2 gm of acid per 1 L of broth in 1 h. Finally, a high concentration of lactic acid is required to give maximum efficiency. In order to maintain the bacterial cell growth different methods of neutralization or extraction of the lactic acid is required to produce either all hydroxyl or all carboxyl groups (Carlotta, 2001).

After lactic acid synthesis it is dimerized and purified using reactive distillation. The separation of lactic acid from the broth is done by adding calcium hydroxide or calcium carbonate in the presence of a small amount of multifunctional hydroxyl compounds such as 2-butene in order to neutralize the fermented acid and give the soluble calcium lactate solutions. This calcium lactate solution is filtered with addition of 1,4-diol, glycerol, or 1,4-butanediol in order to get preferential hydroxyl end-groups. The purification can also be conducted post condensation to remove all the cell biomass alongwith other insolubles, after which the solutions are evaporated, recrystallized, and acidified yield the crude lactic acid (Carlotta, 2001).

PLA is then formed by polymerization. The two general polymer synthesis routes for PLA include the condensation polymerization of lactic acid and the ring-opening polymerization of lactide (Jamshidian *et al.*, 2010). The biosynthesis of PLA is given below in (Fig. 3).

Polymerization of Lactic Acid

As discussed earlier synthesis of high –molecular weight PLA follows different routes. The polymerization methods are given below in (Fig. 4).

Condensation polymerized lactic acid has low molecular weight which could be increased to high molecular weight by using chain extending agents. Esterification and use of coupling agents are also used to increase the molecular weight. However these addition products used for increase of molecular weight of the PLA generates byproducts which should be removed or neutralized. The method of ring opening polymerization or ROP also yields high molecular weight PLA. This method was the only method of producing pure, high-molecular-weight PLA until Mitsui Toatsu Chemicals recently commercialized a process wherein lactic azeotropically dehydrated in a refluxing, high-boiling, aprotic solvent under reduced pressures in order to obtain PLA with an weight-average molecular > 300,000 (Carlotta, 2001).

Processing of PLA

The main conversion methods used nowadays is melt processing. Melt processing involves heating of the polymer over its melting point and then shaping the melt material in desired shapes and sizes and then cooling it into required dimensions. The melt rheological,

Fig. 3 Schematic representation of biosynthesis of PLA. Reproduced from Gupta, B., Revagade, N., Hilborn, J., 2007. Poly (lactic acid) fiber: An overview. Progress in Polymer Science 32, 455–482.

Fig. 4 General methods of PLA polymerization. Reproduced with permissions from Lim, L.T., Auras, R., Rubino, M., 2008. Processing technologies for poly (lactic acid). *Progress in Polymer Science* 33, 820–852.

thermal, crystallization behaviours of the polymer should be known properly in order to process and optimize the products. Melt processed PLA products include injection molded disposable cutlery, meltspun fibers for nonwovens, extruded cast and oriented films, textiles and carpets thermoformed containers and cups, injection stretch blown bottles. The less conventional products made from PLA includes housing for laptop computers electronic. A processing of PLA bottle by Injection stretch blow molding is given in Fig. 5.

PLA is also used with other polymers to form blends and with fillers like nanoclays, biofibers, cellulose, glass fibers etc. to form composites which possess various unique properties.

Applications of PLA

PLA has great application potential for packaging materials ideally for fresh products whose quality will not be damaged by oxygen permeability of PLA. It is the new “green food packaging polymer”. PLA containers which are thermoformed could be used in markets for containing fruits, vegetables and salads. 70% of PLA used today are in packaging. By 2020 PLA is seen to be use more in manufacturing of fibers and fabrics. PLA being a biocompatible polymer has usage in various biomedical applications, mainly used as internal body components like screws in ankle, knee and hands. It is also used as tacks and pins for ligament attachment, plates and screws for craniomaxillofacial bone fixation, interference screws in ankle, knee and hand, rods and pins for bones, and also for surgical sutures, implants, and drug delivery systems (Jamshidian *et al.*, 2010).

PLA Blends

Blends have great application potential in polymer industry. Many studies have been conducted where PLA has been blended with poly (vinyl acetate), thermoplastic starch, poly (ethylene glycol), poly (ethylene oxide), poly (ϵ -caprolactone), poly (hydroxy butyrate), cellulose acetate, poly (butylene succinate) and poly (hexamethylene succinate). Plasticizer like low molecular weight oligomeric lactic acid, glycerol, triacetine, and low molecular weight citrates have been used in these blends. The polymers are chosen depending on the requirements of application. Depending on the applications only non-toxic substances should be used in these blends. The plasticizer used should be miscible with PLA in order to create a homogeneous blend. The plasticizer should also be non-volatile so that it does not cause evaporation at higher temperature during processing. Again the plasticizer should not be prone to migration of materials when in contact. Sometimes plasticizers migrate to the surface of the polymer which could be averted by increasing the molecular weight of the plasticizer. The final properties of the blends depends on various factors mainly the chemical structure of the components, the mixing ratio and the processing parameters (Jamshidian *et al.*, 2010).

PLA Composites

As discussed earlier, rapid use of plastic based products specially polymer composites in almost all aspect of human activities leads to contamination of environmental components like water resources and soil with residual plastic. Thus, researchers are trying to find an alternative renewable solution to these polymer composites by producing bio based polymer composites like PLA composites. Various types of these composites depending on the reinforcement used having various applications can be manufactured. Research work on different types of PLA composites and their potential applications are discussed in detail in the following sections. Manufacturing of these bio-based composites from a biopolymer leads to reduction in conventional polymer production and in return mitigates the GHG's emissions.

PLA-Natural Fiber Composites

Natural fibers are have been used as raw materials to produce biocomposite for replacing the plastic. Copious amount of literature are available where natural fibers has been used to produce reinforced bio-based polymeric composite (Pracella *et al.*, 2016; Pickering *et al.*, 2016). This becomes trends due to inexpensive nature of natural fibers than the synthetic fibers. Also, natural fibers have low density, high specific strength and stiffness, and they contain different types of functional groups easy to modification (Pickering *et al.*, 2016). Mechanical properties of different natural fibers are presented in (Table 1). However, hydrophobicity of natural fibers makes them less useful for preparation of hydrophobic composite. Thus it is necessary either to use some hydrophobic agent or modification of the natural fibers surface to increase the hydrophobicity. Poly-lactic acid (PLA) has been used by many researchers to prepare hydrophobic natural fiber reinforced composites. Selected examples of natural fiber reinforced PLA composite have been discussed below in (Table 1).

Flax Reinforced PLA Composite

Possibility of using flax fiber reinforced PLA composites in automotive industries is monitored in a recent study. To prepare flax-PLA composite, 30% (volume fraction) flax fibers were scatter randomly within PLA polymer and the mixture was used to

Table 1 Mechanical properties of natural

<i>Types of fibers</i>	<i>Density (g/cm²)</i>	<i>Young's modulus (GPa)</i>	<i>Tensile strength (MPa)</i>	<i>Elongation at break (%)</i>
Bamboo	0.6–1.1	11–17	140–230	NA
Carbon	1.4	230–240	4000	1.4–1.8
Coconut	1.15	4–6	131–175	15–40
E-glass	2.5	70	2000–3500	2.5
Flax	1.54	27.5–85	345–2000	1.2–3.8
Hemp	1.47	17–70	368–800	1.6
Jute	1.44	10–30	393–773	1.5–1.8
Kenaf	1.2	14–53	240–930	1.6
Nettle	1.51	24.5–87	560–1600	2.1–2.5
Ramie	1.5–1.56	27–128	400–1000	1.2–3.8
Sisal	1.45–1.5	9–22	350–700	2–7

prepare the composite by film stacking technique (Bodros *et al.*, 2007). The composite were then compared with polypropylene (PP)–flax composites by monitoring the tensile strength and Young's modulus. The report indicated that the mechanical properties of flax-PLA composite were better than the PP–flax composites. Even the properties were very close to mechanical properties of glass fiber polyester composites. In another study, PLA was first modified with Biomax Thermal 300 and Palaroid BPM-500 through melt-compounding and then used to prepare composite with nonwoven flax fibers mat (220 g/m²) (Siengchin, 2014) via hot compression molding. The results indicated that the stiffness of the composite was increased due to flax mat incorporation. Also the composite was resistant to high impact. Researchers have also modified flax fibers to improve their physico-chemical properties by modifying them by alkali treatment, corona discharge, maleic anhydride grafting and aminopropyltriethoxysilane treatment (Xia *et al.*, 2015), and interstitial polymerization (Shanks *et al.*, 2006).

Kenaf-Pla Composites

Kenaf-based PLA composites have been developed by many researchers till date. These types of composites are being used by Toyota for automotive applications. Lee *et al.* (2009) fabricated PLA–kenaf composites by carding PLA with up to 70 wt% kenaf fibers followed by treatment with 3-glycidoxypopyltrimethoxysilane. Thereafter, it was hot-pressed to obtain composites. The report indicated that use of silane coupling agent improve heat deflection temperature and mechanical properties, and reduce water swelling in comparison to the raw PLA. Also it was noticed that fiber diameter has significant effects on thermo-mechanical properties and crystallization rate of the composites.

Glass Fibers-Pla and Carbon Fiber-Pla

Glass fiber is the most common and widely use reinforcement used in composite industries. However, it is noticed that very few literatures are available where glass fibers has been used for composite preparation using PLA. Glass fibers (GF) reinforced composite of PLA could overcome the shortcoming of raw PLA composites as GF-PLA composite has very high mechanical and thermal properties can could replace the petroleum-based plastics (see “Relevant Websites Section”, last accessed Dec 15, 205). These composites due to their performances overcome partially the shortcomings of unmodified PLA because they have the mechanical and thermal properties necessary to allow their using as eco-friendly alternative to reinforced. It has been reported that bioactive glass fibers (BGF) have been used to prepare composites for biomedical application. Studies indicated that use of 40% BGF as reinforcement could improve the mechanical properties of PLA composites by two times (Ahtiainen *et al.*, 2015). The report also indicated that the mechanical strength is comparable to the bone tissue.

Carbon fibers (CF) could be a promising reinforcement agent for preparation of biomedical composites as it has excellent tensile strength, low density, high thermal and chemical stability and electrical conductivity. Carbon fiber has been used extensively for preparation of composite with PLA for use in biomedical application.

Pla-Cellulose and Other PLA Composites

Cellulose extracted from different natural fibers in different forms like micro fibers, microcrystalline, Nano whisker and nanocrystal had been used as reinforcement for preparation of PLA composites (Ambrosio-Martín *et al.*, 2015; Graupner *et al.*, 2016; Oksman *et al.*, 2016; Dhar *et al.*, 2015). Cellulose-reinforced composites are lightweight, biodegradable, non-toxic, low cost and recyclable. However, use of cellulose as reinforcement has drawbacks like hydrophilicity and low processing ability. But, the promising part of cellulose fibers is that the surface hydroxyl groups are easily modifiable. In a study, recycled wood fibers have been utilized to prepare PLA based composites with small amount of silane using injection molding machine. The results indicated that the tensile modulus and the storage modulus of composites increased with the RWF content. Costes *et al.* (2016) have used phosphorylated nano cellulose for preparation of composites with fire retardant properties. They introduced

phosphorus into the nanocellulose either by chemical grafting or by co-additive melt blending using aluminum phytate. This study reported that composites prepared with 20 wt% phosphorylated nanocellulose had better fire retardant properties than the other composites.

PLA Composites With Inorganic Fillers

Fillers are combined with the polymer either for reduction of the cost or for modification of physical, mechanical, rheological, and other properties (see "Relevant Websites Section" last accessed on April 16, 2018). However, the addition of filler should not decrease the molecular, thermal and mechanical characteristics of the composites. Different types of fillers such as talc, carbonaceous fillers, hydroxyapatite, inorganic carbonates and sulfates, mica, kaolin, organo-modified layered silicates, graphite derivatives, carbon nanotubes, sepiolite, halloysite, polyhedral oligomeric silsesquioxanes, silica, ZnO had been used to modify PLA (Murariu and Dubois, 2016; Ojijo *et al.*, 2014; Matusik *et al.*, 2011). Few examples of the filler modified PLA based composites have been described in the following subsections.

PLA-talc composites

Talc is one of the most considered filler material have been used to modify PLA composites. Addition of talc in PLA, increase stiffness, heat resistance, dimensional stability and, reduce crystallization and molding time, and production costs of PLA composite preparation. Copious amount of literature are available where talc has been used as filler to improve the properties of PLA composites (Ouchiar *et al.*, 2015; Kaynak and Erdogan, 2015; Joseph *et al.*, 2015; Refaa *et al.*, 2014a,b; Nofar, 2016; Zhu and Avakian, 2015; Hoekstra *et al.*, 2014). From many reports it is evident that whatever loading amount, talc has nucleating effect which enhance the PLA crystallization (Ouchiar *et al.*, 2016). It is noted that isothermal crystallization halftimes of PLA were decrease almost 65-times by addition of only 2% talc. Due to faster crystallization the processing of composite need less time, key-parameter for determining the level of resistance at high temperature. Also, talc has reinforcing effect which enhances the thermal stability and heat distortion temperature of highly filled composites. In a recent study 30 wt% ultra-fine talc has been used to prepare PLA composites (Shakoor and Thomas, 2014). The mechanical and thermo mechanical characterization of the composites indicated that Young's modulus was increased from 4.1 to 9.8 GPa after the PLA was modified with 30 wt% talc. The enhanced storage moduli of the 30 wt% talc-PLA composite also confirm the reinforcing effect of talc based filler.

PLA-carbonaceous fillers

Technological potential of carbonaceous fillers like carbon black, graphite derivatives, carbon nanotubes, for different applications makes them a promising and attractive alternative to modify polymer based composites (Kasgoz *et al.*, 2014). Large numbers of reviews are available on carbonaceous fillers based composite synthesis and their structural and mechanical characterizations (Mittal *et al.*, 2015). PLA had been used very often as polymeric matrix for production of micro or nano filler based composites (Wu *et al.*, 2015). It is reported that the composites prepared with PLA and carbonaceous fillers had improved nucleating, mechanical, and thermal and fire retardant properties (Murariu and Dubois, 2016). In addition, it was also reported that combination of two or more nano fillers with different geometry showed dramatic improvement of specific properties of PLA composites. For example, Wu *et al.* (2015), enhance conductivity of PLA foams by combining CNT and CB with PLA in different proportion. The CNT form a bridge for connecting CB and forming a better structure network for electrical conductivity. However, the dispersion state and surface functionality of CNT has very important role for the final morphology, electrical percolation threshold and thermal stability of these types of PLA composites.

Recently graphite and its derivatives have been gaining much attention to the composite industries for preparation of micro or nano composites with specified properties (Sullivan *et al.*, 2014). Graphite derivatives like graphene or graphene oxides are exotic materials of 21st century with exceptional charge transport, thermal, optical, and mechanical properties. These types of fillers can be used when properties like heat stability, lubricant ability, thermal and electrical conductivity need to be increased into the composites (Xiao *et al.*, 2014). The study reported by Kim and Jeong (2010) indicated the preparation of PLA nano composites with graphite and exfoliated graphite via melt-blending method. From the report it is evident that the nano-composites had better morphology, thermal, mechanical and electrical properties than the raw PLA composites.

PLA-hydroxyapatite

Hydroxyapatite (HA) has very high bone bonding ability and osteoconductivity. These properties led the use of this filler in the composite industries for biomedical applications (Water *et al.*, 2015) affect copolymer type, HA loading and surface modification HA on the mechanical and microstructural properties of the composites had been studied. The report indicated that surface modified HA containing PLA composites had the better mechanical properties than the raw PLA composites. However, it is fact that the mechanical properties of the composite with HA fillers are still the below the required demand.

PLA composites with other fillers

Apart from the above filler, many other micro or nano fillers such as layered silicates, mica, kaolin, zeolites, glass beads/microspheres (Malinowski *et al.*, 2015), wollastonite, boehmite alumina (Hao *et al.*, 2016; Agwuncha *et al.*, 2015), has been used to prepare PLA based composite with better thermal and mechanical properties.

Nevertheless, it should be mentioned that not all types of filler could improve the properties of PLA based composites. There are many metal oxide based fillers, such as CaO, MgO, ZnO, or layered double hydroxides, which leads to advanced degradation of PLA chains and sharp reduction of thermo-mechanical properties of the matrix.

Conclusions

PLA is a biodegradable, biocompatible polymer derived from renewable sources. Its polymer component lactic acid is derived from vegetable feedstocks by fermentation by microorganisms (*Lactobacillus sp.*) which is then purified and made to undergo polymerization processes like condensation and ring opening polymerization to synthesize the polymer of desired molecular weights. These polymers could be melt extruded or injection molded to form various materials with tailor made properties. They find applications in packaging industries and also in produces biomedical devices, implants etc. PLA could be blended with other polymers using plasticizers to get materials with desired properties and also could be reinforced with various fibers and fillers to form composites. Thus this green polymer and its composites and blends gives a world a wide array of plastic products which can easily replace the conventional non-biodegradable plastics from petroleum sources. Thus, its production from a bio-source reduces GHG's emissions, as in the case of petroleum based polymers. It also recycles renewable feedstocks. The PLA products are also biodegradable after its use and do not require incineration. This also further reduces GHG's emissions. Therefore, use of PLA products will offer the world a way of mitigating GHG's emissions and reduce carbon footprint.

Nomenclature

EJ Exajoule, Unit of energy, 1 Exajoule = 10^{18} joules

GWth Gigawatts-thermal

Kg min⁻¹ Kilogram per minute, Unit of mass flow rate

L min⁻¹ Liter per minute

Mb d⁻¹ Millions of Barrels per day, Unit of volume,
1 barrel = 159.0 L

MTOE Million tonnes of oil equivalent, TOE: tonne of oil
equivalent, unit of energy, 1 TOE = 41,868,000,000 joule

Nm Nano-meter, Unit of length

Petawatts Unit of power measurement,

1 petawatt = 10^{15} watt

PPM Parts per million, also expressed as milligrams
perliter, Unit of concentration

W m⁻² Watts per square meter, Unit of irradiance

W/m-K Watts per meter-kelvin, Unit of thermal
conductivity

Wh m⁻² Watt hour per square meter, Unit of irradiance
over a time period (1 h)

Wt. Unit to measure weight

Introduction

Energy is the primary mainstay of modern civilization. The proper utilization of available energy resources is the key of the development of society. Most of the energy sources which are non-renewable in nature are depleting gradually whereas the consumption of energy rises exponentially with the widespread urbanization throughout the globe. For example ancient people used wood as the major resource of their energy need. Later transition to coal as a major fuel took place. Since the last century widespread use of liquid fuel and gaseous fuel in different purposes has been witnessed. Several reviews (see "Relevant Websites section") indicate that the consumption of energy will increase continuously and this seems logical as more and more urbanization and energy consuming industries are coming up. Progress of civilization will continue and it is one of the aims of modern science and technology to bring the under privileged sections of the society in to the main stream civilization. However all these developments must be sustainable otherwise in near future we will witness extreme dearth of fuels and energy resources. We do not have any right also to exhaust the storage of fossil fuels for our own need without caring for the future. It is high time to think about the alternative energy resources to meet the ever-increasing demand of energy and at the same time should be sustainable. Each of the statistical review (see "Relevant Websites section") indicates a huge difference between consumption and production thus a severe problem of energy crisis for near future is predicted. Besides, air pollution, acid rain, ozone-layer depletion and climate changes are resulted from rapid consumption of fossil fuels which cause disasters like droughts, heat waves, flood causing serious problems like global warming (Gorji and Ranjbar, 2017a).

We need to think of the renewable energy technologies in order to compensate the ever-growing energy demand and also to produce energy in an environment friendly way. There are different renewable energy resources which can be naturally replenished on a human timescale, such as (1) wind energy (2) tidal energy (3) solar energy (4) geothermal heat waves (5) naturally occurring energy that are wasted as mechanical energy. In several areas mostly for electricity generation, air and water heating/cooling, transportation, non-conventional energy resources are explored by the scientists now a days (see "Relevant Websites section").

In a recent survey report it is shown that renewable resources have contributed 19.2% to global energy consumption and 23.7% to generation of electricity in 2014 and 2015 respectively (see "Relevant Websites section"). According to BP Statistical review, Asia is the leading consumer of oil, coal, hydroelectricity and for the first time in 2016, it has become the leading consumer of different renewable resources of energy in power generation, overtaking Europe and Eurasia (see "Relevant Websites section"). This shows the increasing demand for renewable energy in all over the world. The statistical results indicate the growth of renewable in different countries indicating China to be the leading country on the basis of renewable growth (see "Relevant Websites section").

Amongst all other non-conventional sources, solar energy is the most abundant permanent source of energy on the earth. It is reported that solar radiation coming to the surface of the earth in one year is approximately 3,400,000 EJ which is 7500 times the world's total annual primary energy consumption of 450 EJ (see "Relevant Websites section"). Owing to the unlimited availability and environmental safe nature, solar energy can be sustainably utilized in near future instead of other energy forms and prediction says that, solar energy would supply almost 70% of the world energy consumption by 2100 (see "Relevant Websites section").

Energy Harvesting

The environment surrounding us consists of different forms of energy like thermal, light, wind, mechanical energies etc. but energy available from these sources is often too insufficient in quantity to provide adequate power for variable purposes. Most of the part of

these energies is lost as heat or mechanical energies which cannot be converted to any useful work. It has not been possible to capture such ambient energy efficiently to utilize it in useful purposes till now. Energy harvesting is a procedure to derive and store energy from different external ambient energy resources like solar power, thermal energy sources, kinetic energy, wind energy, salinity gradient etc (see “Relevant Websites section”). Energy harvesting devices are used to capture, accumulate, store, condition and manage energies coming from different ambient resources efficiently and effectively and supply it in an useful form. The concept of crystal radio is one of the earliest ways of deriving ambient power from ambient electromagnetic radiation (see “Relevant Websites section”).

The storage of fossil fuels is limited and the extensive use of fossil fuels causes hazardous diseases along with environmental pollution. Now-a-days, instead of utilizing fossil fuels, energy harvesting through ambient energy resources is motivated by the need of energy production in an environment friendly way besides, efficient utilization of energy derived from renewable energy sources can meet the enhanced demand of energy. The places where remote application is deployed and natural energy sources are inexhaustible in nature, energy harvesting from natural sources is an attractive alternative to wall plug or costly battery installation (see “Relevant Websites section”). Energy harvesting-controlled remote control node is able to be implemented as a self-powered electronic system and multiple energy sources can be utilized to enhance the overall efficiency of the system (see “Relevant Websites section”).

Different Types of Energy Harvesting Techniques

The environment represents an infinite number of ambient energy resources. Through proper utilization of modern technologies, useful power is scavenged from different ambient sources which have attracted the researchers due to its pollution-free energy production in a cost-effective way. Available ambient resources and corresponding energy harvesting technologies are demonstrated at Fig. 1 (see “Relevant Websites section”), (Yildiz, 2009).

After extensive researches, Nanotechnology has been identified as an efficient tool in case of harnessing energy. It has opened many new horizons in field of energy production in efficient but cheapest ways. Researchers are trying to achieve highest conversion from electricity to light with the help of quantum dots (Yang *et al.*, 2014), whereas Nano wire solar cell designed by GASPSOLAR shows two times more light entrapment efficiency compared to the commercial solar cells available in market and this Nano wire made solar cell is 10 times cheaper than PV-solar cells (Anis *et al.*, 2017). The processing of Nano materials is very easy thus energy harvesting through nanotechnology is cost-effective at the same time. Solar Botanic Ltd. has designed an artificial tree made of tiny solar cells, the movements due to wind has been converted to electricity with the help of piezoelectric Nano elements, this new technology has been able to achieve 50% enhancement in efficiency in converting solar and wind energy to electricity (Anis *et al.*, 2017). Spire solar utilizes Nano structured materials along with quantum dots to fabricate efficient Building integrated photovoltaic and Chicago implemented the cost effective solar energy systems thus was named as number one green city by business facilities magazine (Anis *et al.*, 2017). ROYAL DSM KHEPRICOAT invented a new Nano porous anti-reflecting coating to avoid the solar energy losses by reflection thus enhancing the efficiency of solar cells (Anis *et al.*, 2017). California based Phoenix motor uses Nano-structured Lithium Titanate to facilitate the high electrical-charge transfer (Anis *et al.*, 2017), the nanotechnology implemented in such Nano- safe batteries produced high performance vehicles which can be charged in less than 10 min using a 480 V circuit thus indicating the effect of nanotechnology in future vehicles. Recent researches shows that Nano particles while dispersed in a base fluid shows enhanced thermal conductivity thus capable of harvesting energy efficiently from incoming solar light compared to conventional solar cell collectors (Bhalla and Tyagi, 2017).

In 1905, Max Weber mentioned the possibility of ending of fossil fuels in his *Die protestantische Ethik und der Geist des Kapitalismus* (see “Relevant Websites section”). Recent trends shows that the growth in consumption of coal and oil could end by 2020 due to enhanced utilization of renewable energy sources (see “Relevant Websites section”).

The demand of utilization of renewable energy sources has enhanced due to its recyclable, pollution free ways of energy harvesting. Recent reports say that wind power met 42% of electricity demand in Denmark, 23.2% in Portugal and 15.5% in Uruguay whereas solar water heating meets 70% of the global total, 180 GWh in China, hydropower generated 16.6% of worlds total electricity in 2015 and 70% of all renewable energies (see “Relevant Websites section”). Very recent British Petroleum

Fig. 1 A list of available energy harvesting sources. Modified from https://en.wikipedia.org/wiki/Renewable_energy. Yildiz, F., 2009. Potential ambient energy-harvesting sources and techniques. Available at: <http://www.energyharvesting.net/>.

Fig. 2 A list of major solar energy technologies. Modified from https://en.wikipedia.org/wiki/Solar_energy and https://en.wikipedia.org/wiki/Energy_harvesting.

statistical reviews show that power generation through renewable resources enhanced up to 14.1% in 2016 except hydropower thus showing the largest increment on record (52.9 mtoe), Asia Pacific contributed 60% of the growth and China has become the world's largest renewable power producer (see "Relevant Websites section"). Amongst the different sources of renewable energy the much explored and researched one is power generation through solar energy.

Solar Energy Harvesting

At the upper atmosphere, the earth receives 174 petawatts of insolation, 30% of which is reflected back to space while rest of the part is absorbed by clouds, oceans and masses (see "Relevant Websites section"). Now-a-days, this huge amount of inexhaustible, clean and abundant radiant energy is harnessed using different technologies such as solar heating, solar architecture, solar heating, molten solar power plants, photovoltaic and artificial photosynthesis technologies. Depending upon how the solar energy is being captured and converted into effective solar power the solar harvesting technologies are broadly classified into active and passive, the active solar techniques include energy harnessing through the use of photovoltaic systems, concentrated solar power and solar heating systems (see "Relevant Websites section"). **Fig. 2** indicates different kinds of solar harvesting technologies (see "Relevant Websites section"; see "Relevant Websites section").

Solar collectors are the key components of solar thermal utilization systems as its efficiency depends entirely upon efficiency of collector. **Fig. 3** represents different solar collectors (Selvakumar *et al.*, 2010).

United Nations Development Program found annual potential of solar energy was 1575–49,837 EJ on its 2000 World energy assessment indicating annual potential to be several times larger than world energy consumption (see "Relevant Websites section"). Photovoltaic systems uses photoelectric effect to convert light into Direct current. Concentrated solar power systems uses lens or mirror arrangements to focus solar light of a large area into a small beam where a working fluid is used to concentrate the heat and that concentrated heat is used in power plants as heat source. Commercial concentrating power plants were first developed in 1980 s (see "Relevant Websites section"). There are wide range of technologies available for concentrating solar light such as, parabolic trough, linear Fresnel's reflector, Stirling dish and solar power tower amongst which, Stirling shows the highest efficiency (see "Relevant Websites section"). Amongst the non-concentrating collectors, most of the evacuated tube systems are considered to be more efficient per square meter than equivalent flat plate systems based on absorber plate area (see "Relevant Websites section"). Recent reports say that solar generated almost 1.3% of the global power in 2016 indicating the increase of the utilization of solar energy to produce electricity in an efficient way (see "Relevant Websites section"). Direct absorption solar collectors utilize heat transfer fluid to absorb radiant energy and to convert it into thermal energy directly. It has been proved to provide higher receiver efficiency compared to others since it was designed in 1970 (Minardi and Chuang, 1975). To achieve highly efficient Direct absorption solar collector (DASC), we need to improve the optical and thermo-physical properties of the heat transfer fluids. Recent researches have introduced a new working fluid called Nanofluid to be utilized as heat transfer fluid in DASCs. Theoretical predictions and experimental investigations show that nanofluid based DASC shows better collector efficiency compared to flat plate collectors due to enhanced thermo-physical properties of Nano fluid (Liu *et al.*, 2017). This is evident that utilization of Nano fluid efficiently transforms the low grade, dispersed solar energy into high grade thermal energy.

Energy Harvesting Using Nanofluid

Nanofluid

In many industrial applications, traditional fluids such as water, ethylene glycol etc. are utilized for power generation, heat transfer and cooling purposes. Owing to the low thermal conductivity, these fluids cannot be used for high heat exchange rates in thermal

Fig. 3 Different types of solar collectors.

engineering devices. Nanofluid is a new class of fluid that contains Nano-sized particles having one of their principle dimension less than 100 nm suspended in a base liquid, the concept of nanofluid was introduced by Choi in 1995 in Argonne National Laboratory (Choi and Eastman, 1995). Nanofluids find its application in diverse field like energy harvesting, thermal management, Chiller, Power sectors, heat exchanger in grinding due to its novel properties like enhanced thermal conductivity, high surface to volume ratio of the Nano-particles compared to their bulk form, good convective heat transfer coefficient (see "Relevant Websites section"). It has been reported that Nano-sized particles mostly carry their atoms on the surface instead of volume thus allowing thermal interactions between tiny sized particles thus inducing micro-convection which in turn enhances the heat transfer (Das et al., 2006). Particle size, shape material nature, viscosity, Brownian motion, acidity, agglomeration, base fluid nature and temperature influences the heat transfer properties of nanofluid significantly (Reddy and Chamkha, 2016). Different experimental observations indicate nanofluid has an enhanced thermal conducting nature compared to base fluid and this thermal conductivity enhances with particle concentration and temperature (Kim et al., 2007; Beck et al., 2009; Williams et al., 2008; Das et al., 2003; Chon and Kihm, 2005).

Effect of Base Fluid

Different types of base fluids are used to formulate Nanofluid. Thermo-physical properties of base fluid are the key features for determining its impact in forming nanofluid for enhanced heat transferring phenomenon. Amongst three kinds of motion called Thermophoretic, Osmophoretic and Brownian motion, Brownian motion affects the thermal conductivity of nanofluid effectively. It has been found from literature that the possible reasons for enhancement of thermal conductivity of nanofluid are Brownian motion of Nano-particles, liquid layering at liquid-particle interface, Nano-particle clustering effect (Murshed et al., 2008). The base fluids generally used are: De-ionized Water (DI), Ethylene Glycol (EG), Mixture of DI and EG, Therminol VP-1, Syltherm-800, Therminol 55, Engine oil, Ionic liquid etc. Table 1 shows a comparison of Thermo-physical properties of some base fluids affecting nanofluidic heat transfer (Sadeghinezhad et al., 2016), (see "Relevant Websites section"; see "Relevant Websites section").

To be a good base fluid to form effective nanofluid with good thermo-physical properties, it should have high thermal conductivity, low viscosity coefficient, low density and small heat capacity. Amongst these base fluids, Therminol VP-1 is a liquid-vapour phase heat transfer fluid possessing high thermal stability and is suitable to be operated over long periods up to 370–400°C. It is an eutectic mixture of 73.5% diphenyl oxide and 26.5% diphenyl (see "Relevant Websites section").

Therminol 55 is used to be utilized in non-pressurized indirect heating systems. This can be utilized up to 315°C showing good thermal stability, it also possess a wide operating range from – 15 to 550°F (see "Relevant Websites section").

Another heat transfer synthetic fluid that is used to formulate nanofluid is Syltherm 800 which is highly stable, long lasting Silicone fluid utilized for high temperature liquid phase operations. The range of operation for Syltherm 800 is from – 40 to 400°C (see "Relevant Websites section").

Apart from the quality of base fluid another important feature which is essential to form good nanofluid is the dispersion stability of nanoparticles. Strong Van der Waals interaction between nanoparticles causes agglomeration which degrades the stability of Nanofluid. To achieve homogeneous and long-term stable Nanofluid is the greatest problem till now. Chemical and physical treatments like addition of surfactant, pH control, and ultrasonic vibration are the techniques to attain stable Nanofluid. Surfactants like Gum Arabic (GA), Sodium dodecyl sulphate (SDS), Hexadecyltrimethylammonium bromide (CTAB), Polyvinylpyrrolidone (PVP), Oleic acid, Triton X 100 etc. helps to modify the stability of dispersion by its amphiphilic nature.

Nano Materials

Energy harvesting using nanofluid is mainly based on its key feature of enhanced heat transfer capability. Previous literature reviews indicate a strong dependence of heat transfer capacity of nanofluid on morphological variation and phase distribution

Table 1 Thermo-physical properties of common base fluids

Fluid type	C_p (J/Kg-K)	ρ (Kg/m ³)	K (W/m-k)	μ (N s/m ²)/viscosity	Ref.

(Amin *et al.*, 2015; Xie *et al.*, 2002a; Murshed *et al.*, 2005; Maheshwary *et al.*, 2017). Prominent morphological variation of different nanostructures can be observed by varying experimental conditions of different Top-down and Bottom-up synthesis procedures. Some examples of the dependence of morphological variations on variation of synthesis procedures and experimental conditions have been shown below. Fig. 4 presents the FESEM (Field emission scanning electron microscope) image of Nanotube morphology of ZnPc nanomaterial through Solvo-thermal synthesis procedure (Mukherjee *et al.*, 2018).

Fig. 5 shows variation of morphology of graphitic carbon nitride synthesized at various temperature (350–650°C) indicating the effect of temperature on morphological changes (Das *et al.*, 2017).

Fig. 6 shows Morphological changes of Co₃O₄ nanowire grown on carbon fabric for variation of hydrothermal reaction time ((a) and (b) for 3 h and (c) and (d) for 6 h) (Howli *et al.*, 2016).

Fig. 7 represents rGO wrapped Bi₂Se₃ flower like morphology through easy hydrothermal procedure (Das *et al.*, 2016).

Morphological effect on nanofluid

Fig. 8 shows a basic classification of various nanostructures based on the different shapes (see “Relevant Websites section”).

Amin *et al.* (2015) has shown the shape effect on the efficiency of nanofluid based flat plate solar collector using spherical, cylindrical, Blade, Brick, and platelet- shaped Nano materials. Through Timofeeva model, they have shown the thermal conductivity enhancement of Alumina nanofluid corresponding to various shapes. The results obtained by Amin *et al.* indicate the largest thermal conductivity enhancement for Blade shaped Alumina particle based nanofluid.

They have compared their results using Hamilton-Crosser and Timofeeva models. Both results follow the same trend but efficiency enhancement trend remains constant in higher particle concentration in case of Timofeeva model whereas in Hamilton-Crosser, trend raises at higher concentrations.

Xie *et al.* (2002a) showed higher rise in thermal conductivity about 23% for cylindrical shaped particles (600 nm) whereas spherical (26 nm) size gives only 15% for a volume concentration of about 4%. Maheshwary *et al.* studied the effect of size,

Fig. 5 Variation of morphology of graphitic carbon nitride synthesized at various temperature (350–650°C). From Das, D., Banerjee, D., Pahari, D., *et al.*, 2017. Defect induced tuning of photoluminescence property in graphitic carbon nitride nanosheets through synthesis conditions. *Journal of Luminescence* 185, 155–165.

concentration and shape on thermal conductivity of TiO_2 -water nanofluid. Amongst rod, cubic and spherical shaped nanoparticles, cubic shaped morphology with 51.87 nm particle sizes and with 2.5 wt% shows highest thermal conductivity effect due to its high surface area (Maheshwary *et al.*, 2017). Results show that at temperature 353K, thermal conductivity ratio reaches 2.69 for cubic shaped morphology whereas it becomes 1.765 for spherical and 1.966 for rod shaped indicating a prominent relationship of morphology with heat enhancement. Their results indicate a 5.54% contribution of shape factor in thermal conductivity enhancement. Fig. 9 shows FESEM images of different morphology of nanoparticles.

Murshed *et al.* (2005) showed high impact of rod morphology compared to sphere in thermal conductivity enhancement with TiO_2 -DI system. Akbar *et al.* (2017) shows shape effect on heat transfer of nanofluid. Fig. 10 represents the shape and volume fraction effect on effective thermal conductivity variations which indicates platelet shaped nanoparticle shows better thermal conductivity compared to brick and cylinder.

By tuning the optical properties of nanoparticles with variable geometry, solar energy harvesting through collector is a recent trend. Table 2 shows variation of solar absorption efficiency factor with variable geometry of nanoparticles having same surface area equal to a Nano sphere of radius 50 nm (Wang *et al.*, 2018).

Particle size is also an important factor. Relationship of effective thermal conductivity with particle size shows different trends. Kim *et al.* Li *et al.* and Peterson *et al.* showed increasing trend of thermal conductivity with particle size while Yu *et al.* showed negative trend (Kim *et al.*, 2007; Li and Peterson, 2007; Yu *et al.*, 2007). Xie *et al.* (2002b) showed decreasing trend of thermal conductivity with particle size both for ethylene glycol and pump oil for alumina based nanofluid. Beck *et al.* (2009) studied influence of particle size on thermal conductivity by using nanofluid of alumina nanoparticles of wide range of diameter ranging from 8 to 282 nm in diameter and showed a decreasing nature of thermal conductivity with size below 50 nm. But according to Mints *et al.* (2009) at higher temperature smaller sized alumina based nanofluid shows greater thermal conductivity. Chopkar *et al.* (2006) and Colangelo *et al.* (2012) showed enhanced thermal conductivity with reduced particle size.

Material effect

Material is also another important parameter to be considered while preparing nanofluid. In Flat plate solar collector the effect of CeO_2 shows highest Exergy efficiency compared to other oxides like NiO , CoO and ZnO (Alim *et al.*, 2014). Metal nanoparticle unlike oxides show surface Plasmon resonance effect that helps to improve the efficiency of solar collector efficiency by modifying

the optical behaviour. Core-shell arrangement is a new addition to this. Various reviews indicate strong dependence of solar collector efficiency of heat transfer capacity of nanofluidic system on the material choice (Gorji and Ranjbar, 2017b; Kim *et al.*, 2016; Al-Shamani *et al.*, 2016; Alashkar and Gadalla, 2015; Alim *et al.*, 2012).

Nanofluidic Energy Harvesting

Energy harvesting is the efficient conversion of any other form of energy to electricity. The striking enhancement of thermal conductivity of nanofluid attracts researchers to utilize it as heat transfer fluid in different solar collectors instead of less efficient, more costly PV collectors.

Effectiveness of Nano Fluid in Solar Collectors

Nanofluid based solar thermal collector uses nanofluid for efficient heat transfer to harness solar energy more efficiently than conventional solar collectors. A recent report shows 92.9% thermal efficiency whereas water shows only 36.2% as a working fluid (see “Relevant Websites section”).

The benefits of using nanofluid are:

- Entrapping of solar light can be enhanced by tuning and changing the size, shape, volume fraction efficiently.
- Suspended Nano-particles enhances thermal conductivity of entire system due to high surface to volume ratio but at the same time decreases the heat capacity of fluid due to very small particle size.
- Nanofluid can be made optically selective by using the Localized surface plasmon resonance (LSPR) effect of metal Nano-particles, thus can be utilized as an optical filter.

Various ways of energy scavenging through tuneable nanofluidic properties are schematically represented in Fig. 11.

The efficiency of carbon coated cobalt dispersed Therminol VP-1 nanofluid based DASC system is found to be 35% indicating the utility of nanofluid based DASC instead of fossil fuels in near future (Liu *et al.*, 2017). Incorporation of Phase change materials into heat transfer fluid enhances the specific heat of it and thus enhancing the energy harvesting (Liu *et al.*, 2017). Metal Nano-particles owing to their LSPR effect shows effectiveness in enhancing the collector efficiency (Jeon *et al.*, 2016) whereas, spectrum splitting nanofluid based Photovoltaic thermal hybrid solar (PV/T) collectors are well-known for better efficiency than stand-alone PV system (Crisostomo *et al.*, 2017).

Solar collectors in energy harvesting

Solar collectors are designed to collect solar radiation effectively and to convert it into heat which is eventually transferred to the working fluid of a system which is either water or air generally. Nanofluid as working fluid improves the efficiency in a great way. Solar collectors are generally of two kinds- Stationary and Concentrating Solar collectors. Flat plate solar collector (FPSC), DASC, Evacuated tube solar collector (ETSC) are widely used stationary solar collectors which are installed at particular tilt and orientation angles to maximize solar energy harnessing. FPSC are widely used and of less thermal efficiency and outlet temperature but of less complicated in nature. These were first developed by Hottel and Whillier in 1950s (Florschuetz, 1979). A FPSC consists of glass, absorber, insulation, backsheet, riser, header pipes and aluminium rails. Many researchers have investigated the effective way to enhance the collector efficiency as much as possible which leads to the use of nanofluid as working material in collector due to their unique property of enhanced heat transfer. Theoretical investigation of FPSC with alumina-water nanofluid at different concentration (0.5%–2.0%) and at different flow rates (0.5–2 L min⁻¹) shows a maximum 31.6% enhancement in efficiency for 1.5% concentration indicating huge enhancement in efficiency compared to that of pure water as working fluid (Dubey, 2017). Use of hybrid nanofluid instead of nanofluid containing only one kind of nanoparticle is proved to be better in maximizing collector efficiency. Tahat *et al.* used Aluminium oxide and copper oxide based hybrid nanofluid as collector medium (Tahat and Benim, 2017). A mixture of EG and water (25:75 by weight) has been used. Experiment has been conducted for various volume concentrations varying from 0.5% to 2%. Results indicate rise of thermal conductivity with rise of concentration.

The functionalization of alumina nanoparticle with copper causes rise in thermal conductivity as copper has higher thermal conductivity compared to alumina. FPSC efficiency shows a maximum of 52% at 2 vol%. A rise of collector efficiency about 45% in average is observed with hybrid nanofluid having 25: 75 EG and water compared to pure water indicating the utility of hybrid nanofluid compared to normal nanofluid. Said *et al.* analysed the effect of pH controlled nanofluid on collector efficiency (Said *et al.*, 2016b). Both exergy and energy efficiencies are studied for alumina-water nanofluidic system with 0.1 and 0.3 vol% for

Fig. 11 Schematic representation of different ways of energy harvesting through nanofluid of various kinds. Artwork done by Nirmalya S. Das.

13 nm sized nanoparticles. They formulate a stable nanofluid by controlling the pH for 30 days. Flow rates were varied from 0.5 to 1.5 kg min⁻¹. Their results revealed an enhancement about 83.5% of energy efficiency for 0.3 vol% and flow rate 1.5 kg min⁻¹ whereas exergy efficiency reaches to 20.3% for 0.1 vol% and 1 kg/min flow rate. [Table 3](#) shows improvement of stability by pH treatment. As stability is a prime factor for enhancing thermal conductivity of nanofluid so, pH controlling can be effective as is seen from this result.

[Zambolin and Del Col \(2010\)](#) and [Ayompe *et al.* \(2011\)](#) showed that the performance of ETSC is far better than FPSC under same condition. An U tube solar collector consisting of a two-layered glass evacuated tube and a U tube which showed a max of 62.8% efficiency with MWCNT for 0.2 vol% with 20% Propylene glycol (PG) water amongst oxides ([Kim *et al.*, 2016](#)). [Sabiha *et al.* \(2015\)](#) proposed the use of water based Single-walled carbon nanotube (SWCNT) in ETSC where 93.43 % collector efficiency has been found for 0.2 vol% much higher (about 71.84%) than water.

Unlike FPSC and ETSC, in DASC, solar radiation is first absorbed by the outer surface of tube and then is transferred directly to a working fluid through heat transfer by conduction and convection. It shows better efficiency with nanofluid as working fluid. Fang *et al.* explored the effect of GO dispersed nanofluid in DASC ([Chen *et al.*, 2017c](#)). Both thermo-physical and optical-absorption properties are investigated. Photo-thermal conversion efficiency is highest (97.45%) for 0.02% of GO at 30°C. Thermal conductivity of GO sheet-water was explored at 30°C. [Fig. 12\(a\)](#) shows their results on variation of thermal conductivity with mass fraction which indicates an enhancement in conductivity with rise of mass fraction. At 0.1 wt%, thermal conductivity approaches to 0.73 W/m-K whereas, [Fig. 12\(b\)](#) shows enhancement of thermal conductivity with temperature. At 0.02 wt%, thermal conductivity enhances from 0.6718 to 0.8656 W/m-K while temperature is varied from 30 to 80°C.

Thus GO sheet is promising in formulating effective working fluid for DASC for better efficiency. Gorji *et al.* observed the effect of different nanofluids (Graphite, magnetite, Silver based) on DASC ([Gorji and Ranjbar, 2017b](#)). Experiments were carried out under variable volume fraction (5–40 ppm), Flow rates (5–10 ml min⁻¹) and incident fluxes (600–1000 W m⁻²). Results showed maximum thermal and Exergy efficiency for magnetite at optimum volume fraction 40 ppm, flow rate 10 ml min⁻¹ and flux-884 W m⁻² followed by the results of graphite and silver nanofluids.

Table 3 Results showing improvement of stability of Alumina – Water based nanofluid by controlling pH of the solution

Nominal particle size	Zeta potential (mV)	Particle size(nm) from DLS using high pressure homogenizer	pH
13 nm	58.4	106	9.0
13 nm	54.3	109	8.1
13 nm	49.5	123.9	7.0
13 nm	35.9	126.4	6.1

Fig. 12 Experimental results of GO based nanofluid showing variation of (a) thermal conductivity with mass fraction, (b) effect of temperature variation on thermal conductivity. Reproduced from Chen, L., Xu, C., Liu, J., Fang, X., Zhang, Z., 2017c. Optical absorption property and photo-thermal conversion performance of graphene oxide/water nanofluids with excellent dispersion stability, Solar Energy 148, 17–24.

Kasaeian *et al.* utilized parabolic trough collector in a bare glass tube, non-evacuated glass-glass tube and Vacuumed absorber tube based receivers (Kasaeian *et al.*, 2017). Ethylene glycol was taken as a base fluid and 0.2% of silica (inner dia: 6 nm and outer dia: 15 nm) and 0.3% of CNT (inner dia: 4 nm and outer: 10 nm) were taken to form different nanofluidic systems. Amongst all, CNT shows maximum outlet temperature 338.3K and highest efficiency 74.9% in vacuumed glass-glass absorber tube. Compared to bare glass tube, 20% higher efficiency has been noted for vacuum glass-glass absorber. They also calculated optimum volume fraction for highest efficiency in vacuumed glass-glass absorber. For, Nano-silica, it is 70.9% at 0.4 optimum volume fractions and

for CNT, it is 80.7% at 0.5. The detailed studies and results of different researchers on the application of nanofluid in different solar collectors are furnished in [Table 4](#).

Optical Nanofluids in Energy Harvesting

Radiant energy from incoming solar insolation should be efficiently captured and converted into thermal or electrical energy in order to harvest useful energy from solar energy which can be done by modifying the dispersed phase of a nanofluidic energy system or combining different Nano-materials having complimentary optical properties together to produce broadband absorption capability or by utilizing some special optical properties of some Nano-particles it is possible to harvest energy efficiently.

Surface plasmon resonance effect

A resonant oscillation of conducting electrons is seen at the interface of negative and positive permittivity material while stimulated by incident light energy, this effect is known as surface Plasmon resonance effect (SPR), a non-radiative electromagnetic surface wave called surface Plasmon polariton propagates in a parallel direction to the interface between negative and positive interface i.e., metal and dielectric interface, the condition for surface Plasmon to exist is the real part of the dielectric constant of conductor should be negative and its magnitude should be greater than that of dielectric, this condition is seen to be satisfied in case of Infra-red-Visible region for air-metal and metal-metal interfaces (see "Relevant Websites section"). In case of metallic Nano-particles, the phenomenon of collective electron charge oscillation due to optical excitation is known as Localized surface Plasmon resonance effect.

Energy harvesting with metal nanoparticles

The metal Nano-particles which are known as plasmonic Nano-particles are capable of entrapping light energy when excited by LSPR effect. Electric field around these Nano-particles is enhanced significantly causing a considerable amount of heat energy generated in particles ([Duan et al., 2017](#)). Utilizing LSPR effect, solar energy harvesting is possible by solar thermal collector. Nanofluids, while used as working fluid provides an alternating way to enhance light absorption due to LSPR effect thereby enhancing the incoming solar light absorption resulting an enhanced temperature of nanofluid, thus energy can be more efficiently harvested as Photo-thermal conversion efficiency depends sharply on absorption properties of nanofluid. The absorption peak induced by LSPR is highly particle size, shape and concentration dependent so, it is possible to enhance photo-thermal efficiency by proper tuning of these parameters ([Duan et al., 2017](#)).

Du *et al.* investigated the rise of collector efficiency of a DASC due to the LSPR effect induced red-shift at the surface of gold nanoparticles based blended plasmonic nanofluid ([Du and Tang, 2016](#)). Numerical representations of the dependence of variation of morphology and concentration on optical properties are presented here. Results indicate a prominent dependence of enhanced LSPR effect of gold Nano-rods and Nano-ellipsoids on increased aspect ratio (AR). Broad-band absorption covering both visible and near infra-red region, is reported to be achieved with gold nanofluid blended with 20% Nano-ellipsoids of AR=2 and 60% of Nano-rods of AR=5 and 20% of Nano-sheets of l/h (length/height) equal to 7. Nano-sheet is reported to have great potential in solar thermal conversion. Blended system shows an enhancement in solar energy harvesting about 104% compared to gold sphere at low particle concentration. [Fig. 13](#) shows the result of absorption efficiency versus wavelength nature for (a) ellipsoid and (b) rod morphologies.

[Fig. 14](#) shows absorption efficiency of Nano-sheets for different ARs. Results indicate that thinner sheet is more effective in exciting LSPR effect.

Chen *et al.* conducted an experimental study on the size effect of gold nanofluid which shows LSPR effect on the efficiency of both flat and cubic shaped DASC ([Chen et al., 2016b](#)). They have reported an average enhancement of 19.9% in photo-thermal conversion efficiency for cubic while a 21.3% enhancement of the same for flat shaped DASC at a very low particle concentration (0.000008 wt%) indicating a geometry dependence of collector on efficiency. [Fig. 15](#) shows the size dependence on absorbance spectra of gold nanofluid.

The result indicates better absorbance with reduced particle size for flat shaped DASC.

[Jin et al. \(2016\)](#) reported an enhancement of photo-thermal efficiency about 76% for gold based nanofluid at 5.8 ppm and a non-linear increasing trend of it for enhanced particle concentration. [Jeon et al. \(2016\)](#) studied the effect of blended plasmonic nanofluid made of gold Nano-rods at flat plate volumetric solar collector. Amongst three different AR (1.77, 2.73, 4.17), highest extinction coefficient was achieved by 4.17 AR based nanofluid depicted in [Fig. 16](#).

Chen *et al.* reported the effect of Au, Ag and Au-Ag bended plasmonic nanofluid on photo-thermal conversion efficiency due to LSPR effect on metal surface ([Chen et al., 2016a](#)). Both temperature and photo-thermal conversion efficiency was observed to rise with concentration. At 1.75–0.15 ppm, Au-Ag blended nanofluid shows enhanced photo-thermal conversion efficiency 30.97% which is almost arithmetic sum of individual Au and Ag nanoparticles. Au (10 nm) and Ag (30 nm) were slightly spherical and slightly spherical-cylindrical in morphology respectively. [Fig. 17](#) shows the solar radiation spectral intensity and absorbance of Au, Ag and Au-Ag based nanofluid.

Energy harvesting through core-shell geometry

Core-shell structure is a kind of biphasic material which has an inner core structure and outer shell made of different materials. These are well-known for their unique tuneable optical property by choosing appropriate material for core and shell and tuning

Table 4 Solar energy harvesting through different solar collectors utilizing nanofluid

Type of solar collector	Base fluid	Nano-material	Shape and size (nm)	Concentration (%) / flow rate	Heat transfer coefficient/thermal efficiency/nusselt number	Ref
PTSC	Ethylene glycol	Silica and CNT	Cylindrical	Optimum conc. (MWCNT)-0.5 vol (%) (Nano-silicon)-0.4 vol (%)	At optimum conc., thermal efficiency is: (MWCNT)-80.7% (Nano-silicon)-70.9%	Kasaeian <i>et al.</i> (2017)
	DI	α -Al ₂ O ₃	Spherical 20 nm	0.05–0.125 vol%	Overall efficiency: 13.98% (80 LPH/0.125 vol %)	Ajay and Lal (2016)
	Water	Al ₂ O ₃	Spherical	0.1 vol% and 0.3 vol%	Nusselt number enhances by 20% at 0.3 vol%	Jafar and Sivaraman (2015)
	Water	CuO	Spherical Outer dia: 100 nm	0.002–0.008 vol%	Thermal efficiency 52% (at 0.008 vol%)	Menbari <i>et al.</i> (2016)
	DI	CuO	Spherical	0.01% Flow rate: 20 L/h	Efficiency reaches 7.4% (Expt. Result)	Ajay and Lal (2015)
	Water	Al ₂ O ₃ CuO	Spherical 20–30 nm	0.01–0.05 vol% Flow rate: 20–60 L/h	Max efficiency (CuO): 18.4% (at 0.05 vol% & 60 L/h)	Sharma and Lal (2014)
	Water EG	CuO	Spherical 25–55 nm	0.01–0.1 vol% Flow rate: 100–160 L/h	Max efficiency: 6.6% (for CuO-Water)	Kandwal and Lal (2015)
	Water	CuO SiO ₂	Spherical 20–30 nm (SiO ₂) 40 nm (CuO)	0.01 and 0.05 vol% Flow rate: 20, 40, 60 L/h	Max overall thermal efficiency (CuO –based system): 9.57%	Kumar <i>et al.</i> (2014)
	Therminol VP 1 Syltherm-800	Al ₂ O ₃ Cu SWCNT	Spherical cylindrical	–	Max rise in annual energy output: 3.1% (Cu- Syltherm-800)	Alashkar and Gadalla (2017)
	Syltherm-800	Al ₂ O ₃	Spherical	1%–10% (Molar fraction)	Convection coefficient rises by 18% at 5%	Basbous <i>et al.</i> (2015)
	Therminol-VP1	Al ₂ O ₃ Cu CNT	Spherical Cylindrical	0–5 vol%	Thermal conductivity enhancement: 98% (CNT) at 3 vol%	Alashkar and Gadalla (2015)
FPSC	Water	Al ₂ O ₃	Spherical	1.5 vol (%)	Max Efficiency: 31.6%	Dubey (2017)
	EG: water 25:75 (by weight)	Al ₂ O ₃ -CuO (Hybrid)	Spherical	0.5–2 vol (%)	Max efficiency: 52% (For 2 vol%)	Tahat and Benim (2017)
	DI (pH-controlled)	Al ₂ O ₃	Spherical 13 nm	0.1–0.3 vol%	Energy efficiency: 83.5% (0.3 vol%) Exergy efficiency: 20.3% (0.1 vol%) Thermal conductivity: 6.8% (0.3 vol%)	Said <i>et al.</i> (2016b)
	Water	MgO	Spherical 40 nm	0.25–1.5 vol%	Thermal efficiency: 9.34% At 0.75 vol%	Verma <i>et al.</i> (2016)
	Water	Al ₂ O ₃	Spherical 13–20 nm	0.1 vol%	Max Energy efficiency: 73.7% (for 13 nm)	Said <i>et al.</i> (2016a)
	DI	Al ₂ O ₃	Spherical 45 nm	3.0 vol%	Efficiency: 11.7%	Colangelo <i>et al.</i> (2015)

DASC	Water	ZnO CeO ₂ NiO CoO	Spherical	1–4 vol%	CeO ₂ shows highest exergy efficiency	Alim <i>et al.</i> (2014)
	50:50 (EG: Water)	Al ₂ O ₃	Spherical, Platelet, Blade, Cylinder, Brick. 15–80 nm (for spherical)	0–5 vol%	Max efficiency: 60% at 1.0 vol% (For 15 nm)	Amin <i>et al.</i> (2015)
	Water	CuO Al ₂ O ₃ TiO ₂ SiO ₂	Spherical	1–4 vol% (Flow rate:1–4 lit/min)	Highest Thermal conductivity: 43% (at 5 vol%) Highest collector efficiency (at 0.8 vol%) for Blade Highest energy efficiency:38.46% At 2 vol% (CuO)	Alim <i>et al.</i> (2012)
	Water	Graphene oxide	Nano-sheet 0.55–1.2 nm (thickness)	0.02%	Thermal conductivity rises: 84% (30–80°C)	Chen <i>et al.</i> (2017c)
	DI	Graphite Magnetite Silver	Spherical C(40 nm) Fe ₃ O ₄ (15 nm) Ag(20 nm)	5–40 ppm	Max Thermal efficiency: 94.57% (Fe ₃ O ₄)	Gorji and Ranjbar (2017b)
	(H2O:EG) Surfactant Pvp: CuO	CuO	Spherical <40 nm	12.5–100 ppm	Thermal conductivity enhancement: 5.6–13.7% (25–60°C)	Karami <i>et al.</i> (2016)
	DI, EG	PUMWNT	Tubular Outer dia:40 nm Inner dia:8 nm	0.005–0.03 vol%	Thermal conductivity enhancement: 27% (at 0.03 vol %) for DI	Shende and Ramaprabhu (2016)
	(H2O:EG)	CuO	Spherical	100 ppm (Flow rate 0.015–0.025 kg/s)	Collector efficiency enhancement: 17% (at 0.025 kg/s rate)	Karami <i>et al.</i> (2015)
	DI	f-CNT	Cylindrical 10 nm	5–150 ppm	Thermal conductivity enhances by 32% at 150 ppm	Karami <i>et al.</i> (2014a)
	DI EG	N-(RGO-MWNTs)	–	0.005–0.03 vol%	Max thermal conductivity enhancement: 17.7% at 0.02 vol% (DI)	Shende and Sundara (2015)
GCPVT	Water	Carbon-Nano-horn	–	Flow rate: 0–0.06 (g/L)	Max Efficiency: 17% at 0.05g/L	Karami <i>et al.</i> (2014b)
	Water	Graphite	Spherical 50–300 nm	0.0025–0.000025 vol%	At 0.000025 vol% 23% enhancement in energy absorption compared to water	Ladjevardi <i>et al.</i> (2013)

Fig. 13 Results showing absorption efficiency variation with wavelength for gold nanomaterial having (a) ellipsoid and (b) Rod morphology for different aspect ratios. Source: Du, M., Tang, G.H., 2016. Plasmonic nanofluids based on gold nanorods/nano ellipsoids/nanosheets for solar energy harvesting, *Solar Energy* 137, 393–400.

other parameters. Controlled tuning of shape, size and material of both core and shell of a Nano-composite enables the emission wavelength to be tuned over a wide range of wavelengths. Duan *et al.* (2017) developed a hybrid nanofluid made of core-shell nanoparticles of various sizes to observe the overall absorbing performance due to enhanced plasmonic resonance effect. To observe the shift in plasmonic resonance frequency, three different sizes of core-shell are chosen and volume fraction is kept at 0.01. Core is made of SiO_2 and Shell is of Ag. First observation was the effect of fixed shell size (5 nm) and variable core sized (15 nm, 30 nm, 45 nm) particles blended together to form a hybrid nanofluid. Fig. 18 shows the absorbance spectra of variable core sized-structure.

The result indicates that the blended form of different core sized particles allows a broadband absorption compared to single core-shell dispersed nanofluid. Wu *et al.* (2015) explored different composite structures (Si/SiC as core and Au, Ag, Cu and Al as shell) based plasmonic fluid to observe both the optical and radiative phenomenon by varying radius ratio, outer radius and type of material. They reported about the coupling effect induced by the structure capable of influencing the average and near field radiation of plasmonic nanofluid simultaneously. Fig. 19 shows the variation of absorption efficiency while changing the radius ratio t for Si/Au composite at 0.7 vol%.

Result indicates that while enhancing the shell thickness keeping the outer radius fixed, the wavelength of resonance peaks approach towards the resonance peak of pure Au nanoparticle hence, optical absorption is enhanced by the enhanced electric field at resonance wavelength of gold Nano-shell thus by adjusting the radius ratio, LSPR effect can be successfully utilized to absorb solar energy efficiently. Fig. 20(a) represents the dependence of shell material on extinction coefficient with outer radii fixed at 5 nm while Fig. 20(b) shows the effect of core material.

Fig. 14 Experimental results showing dependence of aspect ratio on absorption efficiency of gold Nano sheet. Reproduced from: Du, M., Tang, G.H., 2016. Plasmonic nanofluids based on gold nanorods/nano ellipsoids/nanosheets for solar energy harvesting, *Solar Energy* 137, 393–400.

Enhancement of photo-thermal conversion using gold nanofluids with different particle sizes, *Energy Conversion and Management* 112, 21–30.

The researcher concluded that SiC/Al, Si/Al and Si/Cu are the best candidates for photo-thermal application in solar collector.

Use of complementary combination of nano-materials

Broad-band solar thermal conversion is a must in effective solar energy harvesting. Some of the researchers have introduced the use of a combination of Nano-materials to realize it. They chose two different materials such a way that one of them has a strong optical absorption effect in one region while the other has strong absorption capability in another region thus covering the desired portion of incoming solar spectra that enhances absorption causing efficient energy harvesting. [Chen et al. \(2017b\)](#) introduced the concept of choosing materials having complementary optical absorbing properties and combining them to form two-component nanofluid to access an optical absorption over a broad-range. To utilize the whole of the visible and near-infra-red region, they opted CuO which shows strong absorption in visible region and ATO which shows good absorption in near infra-red region. The solar weighted absorption of the two component fluid was reported 99.6% at 0.1 vol% and the solar utilization efficiency was observed to be 92.5% compared to 81.3% for CuO and 80.7% for ATO nanofluids individually. For two-component system, the ratio of CuO and ATO has been shown as an important factor, if the ratio is 4:6 then [Fig. 21](#) indicates almost 100% absorption of solar irradiation.

Fig. 17 Variation of solar radiation spectral intensity and absorbance of Au, Ag and Au-Ag based nanofluids. Reproduced from Chen, M., He, Y., Huang, J., Zhu, J., 2016a. Synthesis and solar photo-thermal conversion of Au, Ag, and Au-Ag blended plasmonic nanoparticles, *Energy Conversion and Management* 127, 293–300.

Spectrally selective optical filter

The solar energy application where absorption of light from a particular portion of solar spectra is needed for a better efficiency, highly efficient Nanofluid with optically selective nature is a very recent finding of researchers. Using such nanofluids as working fluid in solar collectors such as hybrid PV/T collector an efficient energy harvesting can be obtained (Crisostomo *et al.*, 2017). Tuning particle shape, size and material is the way to achieve spectrally selective optical filter. To overcome the temperature limitations in traditional PV/T collector, An *et al.* introduced the concept of using concentrating PV/T collector with spectral splitting filter (An *et al.*, 2016a). Here Oleylamine based Cu_9S_5 nanofluid works as optical filter in collector. The maximum overall efficiency achieved was reported 34.2%, 17.9% more than that of without filters with a collector temperature more than 100°C . Cu_2S is a kind of nanoparticles that always possess the intense effect of SPR at visible to near infra-red region. The spectral properties can be well-tuned by controlling proportion of Cu defect in crystals. Cu_9S_5 is a representative of this kind of materials able to be utilized for efficient spectral modulation. For spectral-splitting hybrid system, liquid should have large transmittance at visible wavelength and at the same time intensive absorption at Ultra-violet and near-infra-red range. Due to Cu_9S_5 addition, absorption of nanofluid is reported to be enhanced up to 800–1600 nm and lightly at 400–800 nm, as the solar radiation in the range 280–2500 nm accounts for 96% total solar radiation so, the use of Oleylamine based Cu_9S_5 nanofluid proves to be a good spectral-selective filter fluid. Hassani *et al.* (2016a) explored the use of nanofluid as a coolant and optical filter to improve the energetic and ecological performance of a hybrid PV/T system. Here, Ag nanoparticles suspended in water acts as a nanofluid based optical filter as the water molecules absorbs longer wavelengths whereas silver nanoparticles absorbs shorter thus as a whole

Fig. 18 Influence of core size variation on absorbance spectra for a fixed shell thickness of 5 nm. Reproduced from Duan, H., Tang, L., Zheng, Y., 2017. Optical properties of hybrid plasmonic nanofluid based on core/shell nanoparticles, *Physica E Low-dimensional Systems and Nanostructures* 91, 88–92.

Fig. 19 Dependence of absorption efficiency on absorbance spectra for Si-Au composite at 0.7 vol%. Reproduced from Wu, Y., Zhou, L., Du, X., Yang, Y., 2015. Optical and thermal radiative properties of plasmonic nanofluids containing core-shell composite nanoparticles for efficient photothermal conversion. *International Journal of Heat and Mass Transfer* 82, 545–554.

provides a broad band absorption capacity and CNT based water nanofluid serves as coolant. Ag-water absorbs 38% of incident radiation while pure water absorbs only 21% and annual Exergy efficiency is reported to be 1.3 MWhm^{-2} with payback time of 2 years. [Hassani et al. \(2016b\)](#) showed the efficiency of hybrid PV/T collector with thermal and optical nanofluids. Ag-Therminol VP1 forms optical filter to allow absorption of radiation from UV and IR region efficiently and with volume fraction enhancement, electrical efficiency is reported to have enhancement up to 9% (GaAs) and 5.6% (Si-PV Cells). Faiz et al. investigated that by varying nanofluidic layer thickness, Hematite nanoparticle based nanofluid shows most resistance to optical transmittance and Gd and TiN based nanofluid are mostly affected with a rise in volume concentration ([Faiz and Zahir, 2014](#)). Faiz et al. also showed the use of Hematite based nanofluid to serve as long-pass tuneable filter ([Faiz and Zahir](#)). Hematite nanofluid shows great similarity with performance of solid thin film Hematite filter at small particle size and high volume fraction and transmittance is reported to improve at mid and high infra-red region. With enhanced volume fraction, level of transmittance raises.

Solar energy harvesting using different optical properties of Nano-particles has been furnished in [Table 5](#).

Phase change material based nanofluid

A phase change material is a material of high heat of fusion and is capable of storing and releasing large amount of energy while the material undergoes a phase change from solid to liquid and vice-versa (see “Relevant Websites section”). Nanoparticles used to prepare PCM nanofluids/composite are metallic materials like aluminium, copper, silver etc. and non-metallic materials such as

Table 5 List of different optical phenomenon of nanofluid used for solar energy harvesting

Nature of nano fluid	Nano-material	Base fluid	Size (nm)	Shape	Concentration	Result showing Photo-thermal conversion efficiency/Abs. coeff./Extinction coeff./ Evaporation efficiency	Solar collector	Phenomenon involved	Ref
Hybrid	SiO ₂ -Core Ag-shell	Water	Shell:5 nm Core:15–45 nm	Shell	0.01 vol%	With the rise of amount of larger particles, absorption peak enhances from 1.1–2.5 μ m	–	Broadband optical absorption due to blending	Duan <i>et al.</i> (2017)
Two-component Hybrid	CuO ATO	Water	–	–	0.1 vol%	Solar-thermal utilization efficiency: 92.5%	–	Complementary optical absorption	Chen <i>et al.</i> (2017b)
Hybrid	TiO ₂ -core Ag-shell	Water	–	Shell	–	Presence of defects enhances solar weighted absorption coefficient by 12 %	–	LSPR effect	Liu and Xuan (2017)
–	GO	Water	0.55–1.2 nm (width)	Sheet	0.05–0.001 wt%	Photo-thermal efficiency: 97.45% (at 0.02%)	–	Photo-thermal conversion	Chen <i>et al.</i> (2017c)
Nano-composite	Ag-core SiO ₂ -shell	water	–	Core-shell	2.5, 1.9, 1.3, 0.6 [wt%10 ⁻²]	9% more weighted thermal + electrical output is obtained for two most concentrated nanofluids having concentration [At 2.5 wt%10 ⁻² & 1.9 wt %10 ⁻²] Compared to same PV cell at full solar spectrum	Hybrid PV/T	Spectrally selective absorption of solar radiation	Crisostomo <i>et al.</i> (2017)
–	RGO	Water	0.55–1.2 nm (width)	Sheet	0.02 wt%	Photo-thermal conversion efficiency:96.9%	–	Enhanced absorption and photo-thermal conversion	Chen <i>et al.</i> (2017a)
Ionanofluid	SiC	[HMIM] BF ₄	30 nm	Sphere	0.03 wt%	Extinction coefficient rises by 5.8 cm ⁻¹	–	Solar absorption by Ionanofluid	Chen <i>et al.</i> (2017d)
Blended	Au	water	AR (ellipsoid): 2 AR(rod): 5 l/h (sheet): 7	Rod Sheet Ellipsoid	20% of Ellipsoid, 60% of Rod, 20% Sheets	104% enhancement in solar energy harvesting for blended system	–	LSPR effect	Du and Tang (2016)
Oleylamine based	Cu ₉ S ₅	Oleylamine	60.2 nm	Sphere	(22.3 $\pm$ 1.1) to (89.2 $\pm$ 4.5) ppm	Efficiency: 34.2% at 89.2 $\pm$ 4.5 ppm	–	SPR Effect	An <i>et al.</i> (2016a)
Hybrid	Ag-Core TiO ₂ -shell	Water	Ag: (19.7 $\pm$ 1.4) nm TiO ₂ : (2.2 $\pm$ 0.7) nm	Core-shell	25–400 ppm	Evaporation efficiency: 53.9% at 200 ppm	–	Broadband solar absorption due to LSPR effect	Li <i>et al.</i> (2017)
Plasmonic	Au	Water	25 nm 33 nm 40 nm	Sphere	0.000008 wt%	Photo-thermal efficiency: 19.9%(Cubic) & 21.3%(Flat)	Flat and Cubic DASC	LSPR effect	Chen <i>et al.</i> (2016b)
Metal Based	Au	DI	20 nm	Sphere	0–5.8 ppm	Photo thermal efficiency: 76% at 5.8 ppm	–	High solar light absorbing capacity due to LSPR effect of Au	Jin <i>et al.</i> (2016)
Blended	AuNR	CTAB	Average dia:16 nm	Rod shaped	<0.0001 vol%	Extinction coeff is highest in largest AR 4.17	FPSC	Broad band absorption over near-IR & Vis spectra due to LSPR effect	Jeon <i>et al.</i> (2016)

Hybrid	Au Cu Al Graphite SiO ₂ /Au	Water	Dia:10–150 nm	Sphere and Shell	Concentration of Au:52% And SiO ₂ /Au: 48%	Enhanced solar light absorption due to hybrid nature	–	LSPR effect	Tullius and Bayazitoglu (2016)
–	Si	Water	40–250 nm (TEM)	Sphere	0.1–0.0001 vol%	Vaporization rate is higher for higher concentration At 1200 s, vaporized weight for 0.01 vol% enhances 1.6 fold relative to pure water & temperature rises 1.8 fold than pure water Si –based nanofluid covers 70% of solar spectrum due to broadband absorption	–	Absorption due to Mie resonance of Nano- particles	Ishii <i>et al.</i> (2016a)
–	CNT Ag	Water	CNT: 15 nm Ag: 10 nm	Cylinder and Sphere	0.0104 wt%	Ag/water absorbs almost 38% of the incident radiation	Hybrid PV/T	Nanofluid serves both as optical filter and coolant	Hassani <i>et al.</i> (2016a)
Plasmonic	Au Ag Au-Ag	Water	Au (10 nm) Ag (30 nm)	Sphere and Cylinder	Ag (0.5 ppm) Au (2.5 ppm)	Photo-thermal conversion efficiency of Ag- Au blended: 30.97% (1.75–0.15 ppm)	–	LSPR effect	Chen <i>et al.</i> (2016a)
Plasmonic	Au	Water	Dia:18.5 nm	Sphere	15 mg/L	At low concentration, an absorption of 80% is obtained after a 10 cm propagation length which is twice than pure water	–	LSPR effect	Mondragón <i>et al.</i> (2016)
Plasmonic	TiN C(Black) Au	Water	TiN:30 nm Carbon: – 40 nm	–	0.0001–0.1 vol%	TiN shows better solar light absorption than others At 0.1 vol%, TiN nanofluid produces almost 240 mg vaporized weight whereas that of carbon, it is less than 220 mg	–	Lossy plasmonic resonance of Nano- particles	Ishii <i>et al.</i> (2016b)
–	Ag	Water	10 nm	Sphere	0.001–1.5 vol%	Optical filter transmits almost 82% of the desired spectrum	PV/T hybrid system	Optical filter	Hassani <i>et al.</i> (2016b)
Plasmonic	TiO ₂ Ag	Water	Shell:30 nm Core size: variable	Core-shell	0.005–0.015 vol%	20.9% photo-thermal efficiency at 0.005 vol% whereas that of water: 15.52%.	–	LSPR effect	Xuan <i>et al.</i> (2014)
Plasmonic	Au	CTAB	AR: 1.77, 2.73,4.17	Cylinder	0.0001vol%	Extinction coefficient: 1.77 cm ⁻¹ in visible spectrum	–	LSPR Effect And Broadband absorption in VIS and Near-IR	Jeon <i>et al.</i> (2014)
Metal oxide based	Al ₂ O ₃ TiO ₂	DI	13 nm 21 nm	Sphere	0.1 vol% 0.3 vol%	Max Extinction coefficient: 11.4 cm ⁻¹ at 400 nm at 0.1 vol% (TiO ₂)	–	Energy absorption depending upon size, shape & different scattering modes	Said <i>et al.</i> (2014)
Metal oxide based	TiO ₂ C- TiO ₂	Water EG	TiO ₂ :42.77 nm C- TiO ₂ : 49.74 nm	Sphere	0.04–0.08 wt%	C- TiO ₂ shows full absorption compared to TiO ₂ in the range 460–800 nm	DASC	Carbon enhances absorption in C-TiO ₂ nanofluid	Subramaniyan <i>et al.</i> (2016)
Metal oxide based	Al ₂ O ₃	0.0001 M aqueous Solution of HCl	13 nm	Sphere	0.03–0.08 vol%	Extinction coefficient reduces more rapidly for 0.05 vol% samples than others within 6 h of nanofluid preparation.	–	Time varying optical behaviour of nanofluid	Sajid <i>et al.</i> (2014)
						Transparency of EM waves raises by 10%–35% within 6 h after preparation within Vis to near IR range			

(Continued)

Table 5 Continued

Nature of nano fluid	Nano-material	Base fluid	Size (nm)	Shape	Concentration	Result showing Photo-thermal conversion efficiency/Abs. coeff./Extinction coeff./Evaporation efficiency	Solar collector	Phenomenon involved	Ref
Plasmonic	Ag	DI	10 nm	Nearly spherical	0.0001625–0.065 vol%	144% enhancement in thermal energy storage is obtained at peak temperature at 6.5 ppm	DASC	SPR effect	Bandarra Filho <i>et al.</i> (2014)
–	Hematite silicon gadolinium TiN	Water	Variable	–	Variable	Maximum transmittance of Gd: 98.9% at thickness 1 μm & 50 vol%	–	Nanofluid acting as tuneable optical filter	Faiz and Zahir (2014)
Plasmonic	Ag	Water	Average size: 49 nm	Near-spherical	20.24–80.94 ppm	After 5 min irradiation the efficiency of Ag nanofluid reaches to 84.61% at 80.94 ppm	–	LSPR effect	Chen <i>et al.</i> (2015)
Plasmonic	Ag Au	Water	Dia: 5 nm (Au & Ag both)	spherical	0.00019 vol% 0.00025 vol% (Experimental)	Ag based nanofluid shows highest thermal, PV & overall efficiency	PV/T Hybrid collector	Optical Filtration of Nanofluid	Saroja <i>et al.</i> (2015)
Hybrid	Au Silica	Water	–	Nano-shell: Silica core & Au shell Nano-matryoshka: Core-Au, Silica-shell & Au-shell	Variable	Ratio of scattering to absorption efficiency: 10 (Nano-shell) and 0.167 for nano-matryoshka multiple scattering begins to effect fractional light absorption for Nano-shell & Nano-matryoshka at 10^9 & 10^{10} NP/ml respectively	–	Large temperature is obtained due to concentrated light obtained by multiple interactions due to strong optical scattering	Hogan (2014)
Plasmonic	Si/SiC Au Ag Cu Al	Water	Outer radius: 5 nm Core Size: variable	Core: Si/SiC Shell: Au, Ag, Cu or Al	0.1–0.7 vol%	Si/Al & SiC/Al Nano-particles are considered to be the best in efficient photo-thermal conversion efficiency	–	LSPR effect	Wu <i>et al.</i> (2015)
–	TiN	Water	30 nm	Spherical	0.0001–0.1 vol%	Evaporation rate enhances four times compared to water whereas heating rate enhances twice at 0.1 vol%	–	SPR effect of TiN	Ishii <i>et al.</i> (2015)
Plasmonic	Au, Ag, Al or Cu and Si	Water	Variable	Core: Si Shell: Au, Ag, Al, Cu	Variable	Al & Cu based core-shell suspension shows better Solar weighted efficiency compared to Nobel metal core-shell	–	SPR effect	Lv <i>et al.</i> (2013)
–	Hematite Fe_3O_4	Water	Dia: 0.005–0.2 μm	–	70–0.1 vol%	Small size, higher concentration & lower thickness of liquid layer shows best transmittance effect	–	Nanofluid as Long-pass tunable filter	Faiz and Zahir (2013)
Plasmonic	Shell: C Ag, Au, Al, Cu, Ni and Core: Si	Water	For core-shell (r1/r2): 0.5, 0.7, 0.83, 0.88 (variable)	Core-shell	0.004–0.008 vol%	Core-shell structure shows highest solar weighted absorption efficiency: At 0.008 vol% and 18 nm net size with 3 nm shell thickness	DACS	Plasmon resonance effect	Lv <i>et al.</i> (2012)
Plasmonic	Au Ag Si	Water	Relative core-radius varies from (0.01–0.99)	Core-shell	9E^{-6} to 7.8E^{-6}	Au/Si with core radius 37.6 nm & 2.4 nm shell thickness & Ag/Si of 10.8 nm & 49.2 nm shell thickness causes 95% of total extinction at a least volume fraction 9E^{-6} to 7.8E^{-6}	–	Plasmon resonance effect	Hewakuruppu <i>et al.</i> (2013)

Fig. 22 Variation of stored heat (KJ/Kg) with temperature for base salt mixture $\text{NaNO}_3\text{-KNO}_3$ and other nanofluids. Reproduced from Chieruzzi, M., Cerritelli, G.F., Miliozzi, A., Kenny, J.M., 2013. Effect of nanoparticles on heat capacity of nanofluids based on molten salts as PCM for thermal energy storage, *Nanoscale Research Letters* 8 (1), 448.

alumina, copper oxide, titanium oxide and carbon nanotubes etc. Kumaresan *et al.* (2012) prepared a new class of nanofluid called NFPCM system by dispersing Multi-walled carbon nanotube (MWCNT) in water with Sodium Dodecyl Benzene sulphonate (SDBS) as surfactant. Results indicate the enhancement of thermal conductivity about 15% at 0.6 vol% of MWCNT thus indicating enhancement of heat transfer phenomenon with concentration. Navarrete *et al.* (2017) introduced the phenomenon of enhancement of both thermal conductivity and heat capacity of nanofluid containing Nano encapsulated Phase change materials (NEPCM). It has been shown here that metal and metal -alloy nanoparticles can be used as self-encapsulated NEPCM system using the metal oxide layer. Therminol-66 has been taken as base fluid. A prominent difference between the performance of base fluid and NEPCM nanofluid with Sn (<300 nm) both in thermal storage and conductivity rise has been presented here. Results showed a significant enhancement in thermal conductivity at 50°C and 100°C at 5 vol% loading.

Chieruzzi *et al.* (2013) developed different nanofluids with phase change behaviour by mixing molten salt base fluid with nanoparticles to study the phase change nature of them and to use them efficiently in concentrating solar plants. The base salt material taken as phase change material was $\text{NaNO}_3\text{-KNO}_3$ (60:40) binary mixture. SiO_2 , TiO_2 , Al_2O_3 , $\text{SiO}_2\text{-Al}_2\text{O}_3$ nanoparticles were used to form nanofluid each in water solution. Results indicate that addition of 1.0 wt% of nanoparticles enhances specific heat of 15%–57% in solid state and of 1%–22% in liquid state. Fig. 22 shows the results representing stored heat versus temperature for $\text{NaNO}_3\text{-KNO}_3$ mixture and nanofluids.

Harikrishnan *et al.* (2013) developed steric acid- TiO_2 nanofluid (average size of nanoparticle was 23 nm) as a composite phase change material to investigate the effect of phase change on solar heating systems. Zhichao *et al.* (2015) explored the heat capacity enhancement of Nano-titania(20 nm) doped erythritol forming Phase change material. The heat capacity of nePCM enhanced by 45% in solid state while 14% in liquid state at 0.2 vol% Nano-titania, thus 8% overall enhancement in total heat capacity storage was reported.

Energy harvesting in a different way

Researchers are paving the path of nanofluidic research with some simple but innovative ideas thus the field of nanofluid in energy harvesting gets wider as time is passing by. Nanofluidic battery is an interesting energy generation system converting mechanical energy to electric power which is possible by the acoustic phonons to drive the condensed ions across a matrix to have sustainable current. Yan *et al.* (2013) studied the effect of slip length and access Ohmic resistance on the energy conversion of nanofluidic battery.

From both the theoretical and experimental analysis, maximum conversion efficiency was found to be as high as 50% for a slip length of 90 nm for a pore radius of 5 nm and pore length of 4 μm . Ouyang *et al.* (2013) designed a Nanofluidic crystal, a high-efficiency and high power density scheme for energy harvesting through reverse electro- dialysis technique.

In predefined microstructure, self-assembly of mono-dispersed nanoparticles forms Nanofluidic crystal (NFC) capable of providing high power output.

The proposed NFC provides a maximum efficiency of $42.3 \pm 1.84\%$ and maximum power density of $2.82 \pm 0.22 \text{ W m}^{-2}$.

Conclusion

More and more use of energy intensive devices and rapid industrialisation all over the world have started taking its toll in terms of increasing greenhouse gas and over all carbon footprint. For a sustainable socio economic development alternative and efficient

energy harvesting technologies have to be developed which can provide clean energy and mitigate the above threats. Use of nanotechnology in the energy fields have already shown enormous promise in this direction. The exciting features of Nanofluid have attracted the minds of researchers to utilize it in harvesting energy from ambient energy sources. Use of Nanofluid as heat transfer fluid in solar collectors has replaced many of the commercial solar cells with its extremely good solar thermal conversion efficiency due to enhanced heat transfer capability of nanofluid. Metal nanoparticle with its unique LSPR effect is able to form an efficient optical nanofluid to capture and absorb incoming solar light effectively and convert it into useful thermal energy. By proper tuning of shape, size and material of a core-shell hybrid nanostructure based nanofluid has proved to be a very good alternative of commercial heat transfer fluid. Besides, blended plasmonic nanofluid is explored extensively now-a-days. Researchers are incorporating different sized metal and core-shell geometry based nanofluid to achieve the broadband solar light absorption both in VIS and NIR region to have enhanced solar energy harvesting. In the present scenario of high energy demand, it is very difficult to fulfil it with only fossil fuel based resources which are depleting gradually. It is high time to think over an alternative way to harvest energy from natural resources in a pollution-free way. Nanofluid is the best option to achieve it economically, without harming our atmosphere. Poor stability, low conversion efficiency are the barriers. Extensive research is needed in this field to achieve higher efficiency and meet the ever-increasing energy demand.

Introduction

Carbon dioxide is considered as a primary greenhouse gas (GHG) of the recent decade as it accounts for 77% of greenhouse effect resulting from anthropogenic activities and 26%–30% of total CO₂ emissions. Burning of fossil fuel is the main source of anthropogenic CO₂ emission. Concentration of CO₂ in flue gas varies with the type of fuel like 12–15 mol% in case of coal, 3–4 mol% in case of natural gas, etc. CO₂ concentration in industrial exhausts are found to vary with the industrial process generating the same and are recorded to be 8–9 mol%, 14–33 mol%, and 20–44 mol% for oil refining, cement production and manufacturing of iron and steel respectively as reported by Songolzadeh *et al.* (2014). Worldwide CO₂ emissions have demonstrated an increase of 26% between 2004 and 2011. Power plants, transportation and industrial processes are respectively responsible for 55%, 23% and 19% of CO₂ emissions in USA. Cement and petrochemical industries are considered as major contributors of global CO₂ emissions (Songolzadeh *et al.*, 2014). According to Intergovernmental Panel on Climate Change (IPCC), the atmospheric CO₂ concentration is expected to reach 570 ppmv by 2100, thereby causing an increase of mean global temperature and sea level rise by 1.9°C and 38 m, respectively (Crombie *et al.*, 2011; Mohammadi *et al.*, 2013). Owing to the rising trend revealed by mean global temperature, IPCC has recommended a reduction in global GHG emissions by 50%–80% to be achieved by 2050 in order to avoid the intense consequences of global warming (Songolzadeh *et al.*, 2014).

In recent times, development of technologies for efficient carbon capture and storage (CCS) is the primary strategy for reducing CO₂ emissions resulting from combustion of fossil fuels and other industrial processes. CO₂ isolated from flue gases may be further reused for advanced oil recovery (Pires *et al.*, 2011). Pure CO₂ is widely utilized in various other industries like food/beverage, production of urea, fertilizer and dry ice, foam blowing and even as a supercritical solvent (Dave *et al.*, 2009; Zangeneh *et al.*, 2011). Therefore, research for CCS is growing by the day. However, most technologies reported so far necessitate improvement in terms of efficiency and reduction of cost incurred (Ben-Mansour *et al.*, 2016). Different post combustion carbon capture processes reported so far have been shown in Fig. 1.

The major challenges limiting conventional strategies of CCS are enlisted as follows:

- Massive consumption of energy (recorded for supplying pure O₂ in case of oxy-fuel combustion capture and compression of captured CO₂ as well as sorbent regeneration in case of post-combustion capture),
- High expense incurred for pre-combustion capture,
- Insufficient technical proficiency,
- Dearth of single compact process with holistic approach for CCS, and
- Non investigation of these technologies for their commercial feasibility and application on industrial scale.

Of all other processes of CCS reported so far, post-combustion carbon capture is considered more advantageous as it is easier to incorporate the same within existing industrial configuration and/or combustion technology of any type and its flexibility exhibited for maintenance and monitoring (Ben-Mansour *et al.*, 2016). Recent research have established nanoporous solids (of both microporous and mesoporous nature), having high surface area and pore volume, as ideal adsorbents for selective separation of CO₂ from a mixture of gases as post-combustion carbon capture (Sneddon *et al.*, 2014). These solids are easy to handle and known to cause fewer corrosion related issues. The schematic comparison of pore sizes of reported nanoporous materials applied for CO₂ capture has been shown in Fig. 2.

Moreover, these materials demonstrate thermal stability up to 150–200°C. This renders them suitable for post-combustion CO₂ capture as the temperature of flue gas generated from a power plant may measure between 40 and 120°C (Sneddon *et al.*, 2014). Nanosorbents prepared from such solids and applied for CO₂ capture have been reviewed in details in the following segments of the article.

Nanosorbents for CO₂ Capture

Metal organic frameworks (MOFs), nanotubes (made up of carbon, silicon carbide, etc.) and nanosheets (prepared from graphene, aluminum nitride, etc.) have been previously reported for CCS with highly reduced energy consumption (Guo *et al.*, 2015). For efficient CO₂ capture, these sorbents are expected to exhibit high surface areas and robust adsorption sites which in turn facilitate high selectivity (Guo *et al.*, 2015). However, interaction between CO₂ and sorbent surface is often weak. Furthermore, in real time scenarios, water vapor often out-competes CO₂ for bonding with active sorbent sites. Some sorbents also reportedly exhibit instability in presence of water vapor (Guo *et al.*, 2015). Efficient nanosorbents for CCS reported in recent studies have been discussed below.

Metal Oxide Nanoparticle

According to contemporary studies, metal dioxides are reportedly exhibit high affinity for uptake of gases like H₂, CO₂, NH₃, etc. due to unsaturated atoms present on their surface (Li *et al.*, 2016). Recent studies have investigated mesoporous transition metal dioxides (like TiO₂, MnO₂, ZnO, etc.) for gas adsorption and sensing (Pawar *et al.*, 2010; Wei *et al.*, 2011). In a recent study by Liao *et al.* (2015), amine-functionalized ZnO nanosheets were investigated for CO₂ capture. In this study, ZnO nanosheets were functionalized with monoethanolamine. The terminal amine groups present on ZnO surfaces were found to facilitate higher CO₂ capture as a result of chemisorption and thereby result in CO₂ activation. The excited ZnO further liberated photogenerated electrons which in turn augmented photocatalytic reduction of CO₂ (Liao *et al.*, 2015).

Some researchers have also suggested that composites of metal oxides formed with carbonaceous materials exhibit improved efficiency for size-selective adsorption of gaseous molecules (Chowdhury *et al.*, 2015; Hong *et al.*, 2012; Li *et al.*, 2015a; Mishra and Ramaprabhu, 2014). In a recent study, Li *et al.* (2016) reported a novel porous nanomaterial consisting of ZnO and N-doped reduced graphene oxide (rGO) referred to as N-rGO-ZnO. N-rGO-ZnO reported in this study was examined for its pore size and adsorption-desorption efficiency for CO₂ and N₂. Addition of ZnO was found to increase the microporous diameter as well as CO₂ and N₂ uptake efficiency of rGO. The CO₂ and N₂ uptake efficiency of N-rGO-ZnO was found to increase with a corresponding rise in temperature and was recorded to be high at 35.84°C rendering the same applicable for capturing CO₂ from flue gas emitted by power plants (Li *et al.*, 2016).

Controlled synthesis and assembly of colloidal clusters of metal oxides nanoparticles are presently being considered as novel building blocks for advanced functional materials (Harada and Hatton, 2015). These clustered nanoparticles are also known as colloidal atoms (Wang, 2010) or supraparticles (Xia *et al.*, 2011) and demonstrate potential efficiency as catalysts (Chen *et al.*, 2011) and high density magnetic storage media (Harada and Hatton, 2015). Harada and Hatton (2015) have reported colloidal clusters of MgO nanoparticles coated with alkali metal nitrates and mixtures of nitrate/nitrite capable of rapid and significant uptake of CO₂. These adsorbents demonstrated significant adsorption of CO₂ at ~300°C and were successfully regenerated at ~400°C rendering the same highly appropriate for treatment of hot gaseous discharges (Harada and Hatton, 2015). The nitrite salts used to coat the MgO nanoclusters were also considered responsible for preventing detrimental morphological alterations resulting from recurring cycles of adsorption and desorption by increasing critical thickness of the sorbent surface.

Mesoporous Materials

Mesoporous substrates (like zeolites, carbonaceous and siliceous materials, MOFs, etc.) having fine structural and chemical properties are considered highly advantageous for carbon capture (Kamimura *et al.*, 2014). These materials have facilitated pressure/temperature swing adsorption of CO₂ from diverse sources of emissions. Synthetic zeolites and mesoporous materials modified with amines demonstrate high selectivity and interact strongly with CO₂. Such materials are therefore considered appropriate for capturing CO₂ from flue gas emitted post-combustion having low pressure and low CO₂ concentration (D'Alessandro *et al.*, 2010; Samanta *et al.*, 2011). Kamimura *et al.* (2014) reported the fabrication of novel mesoporous ceria having a surface area of 200 m² g⁻¹ and investigated the same for CO₂ adsorption. This mesoporous ceria was found to demonstrate significantly higher CO₂ uptake capacity per volume in comparison to commercially obtainable non-porous ceria, activated carbon and zeolite under conditions of high pressure (3000 kPa) and moderate temperature (25°C). The mesoporous ceria reported by Kamimura *et al.* (2014) was found to be highly stable and could be conveniently regenerated after multiple cycles of adsorption-desorption. Results of this study also indicated that a further rise in surface area of mesoporous ceria could facilitate higher CO₂ uptake. The simple and cost effective process of synthesis of mesoporous ceria reported in this study was also considered more advantageous than mass production of other contemporary adsorbents.

In a separate study by Niu *et al.* (2016), authors reported mesoporous silica nanotubes impregnated with polyethenimine as an emerging nanomaterial for CO₂ capture. The specific surface area and pore volume of these silica nanotubes was found to be higher than those of parent halloysite nanotubes by six and two times respectively. Impregnation with polyethenimine was found to facilitate higher CO₂ uptake capacity (around 2.75 mmol g⁻¹ at 85°C for two hours) in the mesoporous silica nanotubes. These polyethenimine bearing mesoporous silica nanotubes demonstrated rapid kinetics and improved stability even after ten recurrent cycles of adsorption-desorption. Authors claimed these nanotubes to be heat stable, ecofriendly, cost effective and highly efficient for CO₂ capture.

Metal Organic Frameworks

MOFs are microporous materials consisting of metal ions or metal clusters bearing organic ligands assembled in suitable solvents (Furukawa *et al.*, 2013; Qiu and Zhu, 2009). MOFs offer high surface areas as well as uniform pore features and are thus widely applied for chemical separation and catalysis (Chen *et al.*, 2010; Lee *et al.*, 2009). MOFs have also been previously investigated for CO₂ capture and clean energy storage. Recent studies have focused on developing novel materials with higher surface areas having enhanced gas loading abilities (Anbia and Hoseini, 2012; Sumida *et al.*, 2011; Xiang *et al.*, 2011). Such materials generally exhibit high sorption enthalpy that renders the same suitable for adsorption of gas molecules. Due to the presence of diverse metal centers

and functional ligands in structures of MOFs these materials are widely considered for development of novel composite materials having improved gas storage ability and properties differing from parent MOFs (Kang *et al.*, 2015).

Improvisation of MOF has been primarily achieved via catenation and interpenetration, enhancement of chemical bonding as well as involvement of electrostatic force (Liu *et al.*, 2012). In a study by Kang *et al.* (2015), adsorption enthalpy of MOF (JUC-32) was reportedly enhanced by composite formation with carboxyl-modified multi-wall carbon nanotubes. Results obtained in this study suggested that composite materials absorbed larger quantities of CO₂ and CH₄ with increased adsorption enthalpies in comparison to individual parent materials.

Other recent studies have also reported different strategies like multipoint interactions, partitioning of pore space, cooperative crystallization (in case of heterometallic MOFs), ion exchange, ligand exchange (post synthesis) and charge polarization, trapping of single molecules, encapsulation of ionic liquids, enhancement of local electric field, controlled morphology, interpenetration of partial framework, controlled co-adsorption of water, etc. for enhancing the capacity of CO₂ adsorption of MOFs (Yu *et al.*, 2017).

Nanoporous Polymers

Metal nanoparticles discussed previously have gained considerable focus owing to their potential utilization for conversion of energy, pollution remediation and catalysis (Kim *et al.*, 2013; Zaera, 2013). However, these nanoparticles tend to aggregate due to high surface energy and thereby suffer from loss of reactivity (Myers *et al.*, 2011). Previous studies have investigated immobilization of nanoparticles on MOFs for fabrication of catalytic systems having high selectivity and reactivity (Aijaz *et al.*, 2012; Roberts *et al.*, 2012; Saha *et al.*, 2013; Zhu *et al.*, 2013). However, reversibility of metal coordination of MOFs renders them unstable in different liquid-phase catalysis (Li *et al.*, 2015b). Recent reports have suggested porous organic polymers (POPs) as a suitable alternative to MOFs for immobilization of nanoparticles due to the similarity of both materials (Dalapati *et al.*, 2013; Hasell *et al.*, 2009; Zhou *et al.*, 2013). The catalytically active sites of POPs can be adjusted and altered with a broad range of organic and synthetic compounds for enhancing their catalytic potentials (Fang *et al.*, 2014; Suresh *et al.*, 2014). The porosity of POPs depends upon the method of POP synthesis as well as the geometry and size of constituting monomers and also influences the catalytic activity of the POPs (Smith and Dichtel, 2014; Wang *et al.*, 2013; Xu and Jiang, 2014). Recent studies have reported the incorporation of functional groups like triazolyl, imine, urea, etc. as linkages in POP for stabilization of immobilized metal ions and nanoparticles (Bhunia *et al.*, 2012; Du *et al.*, 2010; Li *et al.*, 2014).

In a recent study by Li *et al.* (2015b), researchers reported ultrafine palladium nanoparticles separately immobilized on two triazolyl functionalized POPs (CPP-C and CPP-Y) for hydrogenation of olefins. Results indicated good stabilization of immobilized palladium nanoparticles due to combined effect of entrapment in polymer matrix and coordination interaction with triazolyl groups.

In a separate study, Talapaneni *et al.* (2015) reported the confinement of N-heterocyclic carbenes (by virtue of steric interactions) in nanoporous polymer (NP-NHCs) and its subsequent application for CO₂ capture at room temperature. NP-NHCs exhibited highest CO₂ capture efficiency than any other solid carbene based material reported so far. The NP-NHC also demonstrated high activity and selectivity for formation of cyclic carbonates from CO₂. Moreover, results obtained in this study established the reported NP-NHC as a heterogeneous organocatalyst having good recyclability. The metal free integrated approach for CO₂ fixation and conversion reported by Talapaneni *et al.* (2015) was also found to be a novel cost effective approach for CO₂ capture.

Graphene Based Sorbents

A survey of existing literature revealed that carbonaceous materials like activated carbons and carbon nanotubes have already demonstrated promising CO₂ adsorption (Mishra and Ramaprabhu, 2011a; Pevida *et al.*, 2008). In comparison to other carbonaceous materials, graphene reportedly has cost-effective and feasible production procedures, greater surface area, mechanical strength, stability (both thermal and chemical) as well as recyclability and offers good tolerance to chemical alterations (Dai *et al.*, 2009; Ghosh *et al.*, 2008). Recent studies have reported chemically modified graphene to possess excellent CO₂ adsorption capacities (Chandra *et al.*, 2012; Mishra and Ramaprabhu, 2011b). Studies have also suggested deletion or substitution (with nitrogen bearing functional groups) of acidic groups present on the surface of carbonaceous materials for enhancing the CO₂ uptake efficiency of the adsorbent (Oh *et al.*, 2014; Zhao *et al.*, 2012).

In a recent study, Oh *et al.* (2014) have reported borane modified graphene-based sorbents (B-rG-O) for CO₂ adsorption. The B atoms are Lewis acid in nature and their electron deficiency reportedly demonstrate high affinity for the electron-rich O atoms present in CO₂ (Choi *et al.*, 2011). CO₂ adsorption capacity of the reported sorbent was found to be 1.82 mmol g⁻¹ under a pressure of 1 atm. Authors also reported that the charge distribution of the sorbent could be altered by introducing boron defects in the sorbent architecture. The carbon atoms neighboring this defect were found to exhibit improved selectivity towards CO₂.

Similar results were also reported by Sun *et al.* (2014) who had investigated CO₂, N₂, CH₄, and H₂ adsorption using amphoteric B₈₀ fullerene. Results obtained in this study indicated that CO₂ molecules strongly interacted with basic domains of B₈₀ via Lewis acid–base interactions. However, the other gases were found to develop only weak interactions with B₈₀ fullerene. Thus, results suggested that B₈₀ fullerene could be effectively used to separate CO₂ from a mixture of gases.

In a separate study, Mishra and Ramaprabhu (2014) reported Fe₃O₄ decorated graphene nanocomposite for CO₂ capture. The composite reported in this study demonstrated good CO₂ uptake even under conditions of elevated pressure and temperature where graphene usually undergo desorption of adsorbed gases. Adsorption of CO₂ by this composite was chemisorption in nature which in turn promoted higher CO₂ uptake.

Monolayer Boron Nitride

In recent studies, novel hexagonal boron nitride (h-BN) occurring as monolayers has been considered as an alternative to graphene due to similar properties like high stability (both chemical and thermal) and conductivity that rendered the same suitable for catalytic activity (Guo *et al.*, 2015). Owing to the intrinsic iconicity of B–N bonds and high specific surface areas, h-BN sheets are being investigated for separation and storage of gases. According to the results obtained by Guo *et al.* (2015), h-BN sheets can efficiently separate and capture CO₂ from a mixture of H₂, CH₄, N₂, CO, and H₂O in presence of a vertical electric field. In absence of the electric field, h-BN sheets are unable to capture CO₂ due to reduced binding energy and loss of entropy. Hence, it could be concluded that h-BN sheets hold potential for application in field controlled separation and storage of CO₂.

Ionic Liquids

Recent studies have contributed significant attention to imbibition and stabilization of ionic liquids (IL) within channels of different porous substrate for purposes of catalysis and separation (Kasahara *et al.*, 2014; Ramdin *et al.*, 2012; Steinrück *et al.*, 2011). The IL-modified pore structure of supported IL phase materials (SILPs) and membranes (SILMs) are tailored according to their application type (catalytic or separation) (Romanos *et al.*, 2014). Use of nanoporous materials as supports for IL reportedly provides high surface area and stabilizes the IL phase entrapped in the nanopores. For achieving simultaneous dispersion of catalysts and adsorption of gases, the layer of the catalyst bearing the IL phase should be kept as thin as possible for ensuring that the gas reactants are able to access the whole IL surface while passing through the pores. Leaving the core space of nanopores open in SILPs is found to lead to reduced absorption specificity whereas complete pore filling is known to result in diffusivity. Besides nanoporous materials with ordered pore structure (like nanotubes, mesoporous silicas, zeolites, etc.) are rather expensive. Those having complex pore architecture exhibit high tortuosity which in turn hinders efficient gas absorption (Romanos *et al.*, 2014). Romanos *et al.* (2014) have reported “inverse” SILPs in their study whereby micro IL droplets are enveloped by silica nanoparticles. These inverse SILPs were found to demonstrate efficient separation of a mixture bearing CO₂ and N₂. These inverse SILPs were capable of 1.5–3.0 mmol g^{−1} CO₂ absorption under pressure and temperature conditions of 1 bar and 40°C respectively. The kinetics of CO₂ absorption was found to be higher for inverse SILPs in comparison to contemporary conventional SILPs. The significant aspects of these inverse SILPs included convenient handling, reduced cost as well as high CO₂ separation efficiency and absorption capacity. The stability of these inverse SILPs at high temperature and pressure indicated its applicability on an industrial scale for treatment of real flue gas. Moreover these inverse SILPs were completely regenerated at 60°C without any structural alteration.

Nano-Biocatalysts for CO₂ Sequestration

Recent studies have proposed novel methods for CO₂ reduction of which biomimetic CO₂ capture has been considered as one of the most promising approaches due to its low cost and green nature (Jo *et al.*, 2014). In a recent study, Jo *et al.* (2014) reported a biosilica encapsulated carbonic anhydrase biocatalyst for application in environmental CO₂ capture. No leaching of the enzyme was recorded from the biosilica matrix thereby confirming the efficiency of the process. Besides good reusability, these biocatalysts demonstrated good thermostability by withholding 80% of its activity after being stored at 50°C for five days. This biocatalyst exhibited highly compact morphology with low surface area while its outermost surface performed catalytic activities. This biocatalyst was found to exhibit a maximum of almost 60% of CO₂ capturing efficiency of that demonstrated by the free enzyme. Therefore, results obtained in this study suggested that the biocatalysts reported herein could be successfully investigated for biomimetic capture and storage of the CO₂.

In another recent study, Liu *et al.* (2015) reported an artificial process simulating the scheme of photosynthesis facilitating reduction of CO₂ for formation of various biochemical products. In this study, a biocompatible nanowire array capable of capturing light was developed that supported direct interaction with microbial systems. This hybrid semiconductor was investigated for reduction of CO₂ to form different end products like fuels, polymers, pharmaceutical precursors, etc. with only consumption of solar energy. The silicon nanowire array used in this study provided high surface area for trapping light energy required for providing reducing equivalents to *Sporomusa ovate*, an anaerobic bacterium, in order to achieve acetic acid produced photoelectrochemically under aerobic conditions. The acetate so produced was activated to yield acetyl coenzyme A using genetically modified *Escherichia coli* for synthesis of value-added products like n-butanol, polyhydroxybutyrate, and three different isoprenoids. Development of such a biocompatible nanodevice supporting living cells paved the path for designing a programmable system for chemical production entirely powered by solar energy. Results obtained in this study also established a process of

conversion of solar power by integrating nanoscale semiconductors with bacterial biocatalysts. Primary advantages of this device included improved oxygen tolerance, direct utilization of exhaust gas in the system and efficient CO₂ sequestration in nano-wire – bacteria hybrid. Furthermore, this modular design facilitated the synthesis of various molecular targets by a simple integrated system without any changes in the setup used for capturing solar energy and reduction of CO₂ to acetate by altering only the specie of microorganism present downstream.

Conclusion

An efficient adsorbent forms a vital part of almost all CCS technologies developed for separation of CO₂ from pre/post combustion sources like fossil fuels and flue gas respectively. Recent research has devoted significant attention for fabrication of efficient adsorbents having enhanced capacity, stability as well as recyclability. Owing to their high specific surface area, porosity and stability, different nanoporous materials have been investigated for their CCS efficiencies. The present review has covered both advantages and limitations of different nanoporous catalysts reported in the recent decade for their carbon capture efficiency. The nanomaterials discussed in this review may be implemented as sorbents, membranes or molecular sieves for CCS. Biocatalytic conversion of CO₂ for yielding valuable byproducts has also been discussed in this study. The biomimetic carbon capture and utilization technologies discussed in this review was completely devoid of any significant hazard related to CO₂ storage and also provided an opportunity to recover a part of the cost incurred for maintenance of the proposed device by producing value added products. In spite of all endeavors, technologies for carbon capture and storage/utilization are still reckoned as temporary solutions for managing the ever increasing discharge of CO₂ in the environment. In the long run the human thirst for energy has to be satiated by alternative energies instead of fossil fuels. Sources of energy like solar power, wind power, tidal power, hydropower, etc. are considered as potential alternatives of fossil fuel but necessitate caution prior to rapid implementation on wide scale in order to avoid any unforeseen detrimental and significantly irreversible effects. Nevertheless, current technologies for CCS and utilization play a vital role in remediating current environmental conditions till scientists develop novel efficient technologies for generating power with reduced carbon consumption. The nanomaterials discussed in this study may be considered as the most recent and efficient technology for addressing and arresting anthropogenic climate change.

Introduction

From the dawn of civilization, energy has been the sole reason for creating the trajectory of advancement and innovation of the human race. Since 1000 BCE fossil fuels have served as the citadel for civilization and industrialization consecutively. The earth had enough natural fuel reserves to cater to our needs all these centuries but the rapid growth of population and the modern industrial revolution since the past few centuries have cumulatively questioned the sustainability of the natural reserves.

Present studies according to the World Coal Association have given an estimate of 1.1 trillion tonnes of proven coal reserves worldwide. The implication being that the coal reserve can last us around 150 years at current rates of production and consumption. Whereas the world is left with meager 53.3 years to find an alternative to oil and natural gas before the proved reserves run dry according to British Petroleum. Inevitably, the nations are excavating for new reserves and scouting for new methods, but the cost-effectiveness is an elephant in the room. Necessity being the mother of invention has led to the discovery and experimentation of using renewable sources of energy in the form of solar, wind, wave, hydrogen, geothermal etc. to balance the demand-supply ratio. Given the present trends of research in the field of renewable energy, it is expected that almost 50% of the world's energy demands will be satisfied with the aid of green energy by 2040. Moreover, almost 70% of the reduction of excess greenhouse gases can be achieved with this target.

Nanoscience and nanotechnology with their vast and diverse applications have been another rapidly growing area of research and in fact, have shown promising results in experimentations on renewable energy. Nanoparticles being in the size range of <100 nm have a vast impact on the fabrication and utility due to their reduced size. The most notable effects being:

- (1) Lower consumption and dissipation of energy due to a smaller size.
- (2) Ease of synthesis in large quantity.
- (3) Enhanced capability of energy storage.
- (4) Clean and green technology with significantly less waste generated.
- (5) Faster production and easy disposability.

The incorporation of nanotechnology in the alternative forms of energy has improved the efficiency of generation and durability quite remarkably. For example, the use of nanoparticles in solar cells have improved the capacity for energy storage and retainability. The use of nanoparticles adds to the lightness of the rotor blades, hence increasing the efficiency of wind energy generation. Nano-coatings on the surface of the tidal energy generating equipment results in significant corrosion resistance whereas the infusion of nanocomposites in manufacturing drilling machines for the geothermal energy has resulted in an increase of the life-span of machines. Moreover, nanotechnology also paved a path for controlled growth of biomass with proper shielding against the danger of pest and hence creating an increased number of plants for biofuel extraction. This article aims to provide an insight into the diversified applications and impact of nanoscience and nanotechnology in the field of renewable energy generation.

Applications of Nanotechnology in the Energy Sector

Solar Energy Sector

Studies show that the surface of the earth receives about 124 EXA (10^{18}) Watts or 3850 Zetta (10^{24}) Joules of solar power annually (Chapin *et al.*, 1954). The range of solar power spectrum varies from 250 nm to about 2500 nm in wavelength. The chief usage of solar energy is the derivation of electrical energy from it. The two primary methods for the conversion of solar energy to electrical energy are concentrating the solar power by reflectors and using photovoltaic cells.

Nanotechnology is the future of fabricating more efficient and low-cost systems to generate, store and transport energy. Nanoscale level synthesis and designs combined with thin films offer economical solutions to the otherwise sophisticated methods of hydrogen production, photovoltaics, fuel cells, solar thermal systems etc. The solar economy comprises of the various ways by which the solar energy can be used, for example, in PV (photovoltaic) technology for conversion of light to electricity directly, solar collectors, artificial photosynthesis for producing carbohydrates and hydrogen by the water-splitting method, Biomass technology for generating complex carbohydrates to generate biofuels etc (Bailey, 1972).

The photoelectric effect is the principle behind the production of electricity by PV cells. Presently, silicon wafer-based solar cells (thick cells of around 150–300 nm made of crystalline silicon) is the prime available type in the real world. This technology, coined as the first-generation photovoltaic cell, accounts for more than 86% of the global solar cell market. The second-generation

of photovoltaic materials is primarily based on the inculcation of thin film layers (1–2 nm) of semiconductor materials. Nano-crystal quantum dots, which are nanoparticles made of direct bandgap semiconductors serves as the basis to thin film solar cells on silicon or conductive transparent oxide (CTO), such as indium-tin-oxide (ITO) substrate with nanocrystal coating. Photo-catalyzed decomposition of pollutants at various titania surfaces is also of great interest to the present scientists. Electron transfer reactions are the governing factors for these photoinduced processes and hence also the subject of one of the theoretical contributions for the next generation solar cells. Harvesting of light photons in a semiconductor (most commonly TiO_2) and subsequent conversion of these photons to electronic excitations is the typical scheme of photocatalysis which then induces the desired chemical reaction on the semiconductor surface.

The major benefits of incorporating nanotechnology for manufacturing solar cells are:

- (1) Reduction of manufacturing costs of conventional solar cells made of crystalline semiconductor material due to the implementation of low-temperature processes similar to the novel technique of high-temperature vacuum deposition printing.
- (2) Reduction in the installation cost with the aid nanotechnology since it fosters the manufacturing of flexible rolls instead of rigid crystal panels.

Solar Cell Structures and Infusion of Nanoparticles

P-N junction solar cells

The solar spectrum comprises of photons with energies ranging from about 0.5–3.5 eV. Conventional solar-cell technology or the first-generation solar cell generation is based on a single p–n junction that is utilizing one electron-hole pair for each absorbed photon. Electron-hole pairs are generated when light quanta are absorbed and they can reach the junction if their recombination is prevented, where they are separated by an electric field. Large crystals of silicon, or thin films of amorphous silicon, cadmium telluride or copper indium gallium selenide etc. are the chief components of the current photovoltaic technologies. A large part of the solar spectrum is absorbed by the semiconductor material determined by its band gap. For instance, amorphous silicon has a higher bandgap (1.7 eV) than crystalline silicon (1.1 eV), which implies the absorbance of the visible part of the solar spectrum more strongly than the infrared portion of the spectrum (Corkish *et al.*, 2002; Miskovsky *et al.*, 2012).

The p–n junction solar cells based on crystalline silicon currently achieve an efficiency of 22% approximately (Conibeer, 2007; Goetzberger *et al.*, 2003). According to the Shockley–Queisser limit, the maximum thermodynamic efficiency for single bandgap devices, assuming detailed balance is 31% (Shockley and Queisser, 1961). It is obvious that one can improve the efficiency by layering materials with different bandgaps. This is the underlying idea of the multi-layer ‘tandem’ cells, which are highly efficient, but very expensive (Conibeer, 2007). The energy conversion efficiency of solar cells based on bulk silicon is higher than that of thin-film silicon.

These limitations have been countered by employing light-trapping techniques (Goetzberger *et al.*, 2003). The incoming light is obliquely coupled into the silicon film and the absorption is increased multiple folds as the light is made to traverse the film several times (Goetzberger *et al.*, 2003). The thermodynamic limit on light trapping determines the minimum thickness of the material for fabricating the film (Yablonovitch, 1982). However, recent findings reveal that in principle, any semiconductor material can exceed the light-trapping limit if the local density of optical states (LDOS) of its absorbing layer is greater than the LDOS of the bulk semiconductor material (Callahan *et al.*, 2012). This may potentially allow for designing novel solar cells that are approximately 10 nm thick but can absorb light from the entire solar spectrum (Callahan *et al.*, 2012).

Utilization of the electric field effect provides another method to create the p–n junctions in semiconductors, where the application of an electric field alters the concentration of charge carriers (Regan *et al.*, 2012). The major factors that limit the efficiency of conversion are the inability to absorb photons with energy level lower than the bandgap, thermalization of photon energies exceeding the bandgap and the recombination losses due to radiation (Conibeer, 2007). The approaches to counter the loss of efficiency can be attributed as:

- (1) To increase the number of energy levels by stacking of multiple p–n junctions in different semiconductor materials resulting in the absorbance of higher-energy photons in the higher-bandgap semiconductors and lower-energy photons in the lower-bandgap semiconductor (Regan *et al.*, 2012).
- (2) To capture the carriers before thermalization hence yielding a higher photovoltage.
- (3) Multiple-carrier-pair generation per high-energy photon or single-carrier-pair generation with multiple low-energy photons, leading to the enhancement of the photocurrent.

Intermediate-band solar cells (IBSCs)

The main concept behind IBSCs is to introduce one or more energy levels within the bandgap so that they can absorb photons in parallel with the normal operation of a single-bandgap cell (Conibeer, 2007; Luque *et al.*, 2012; Luque and Martí, 2011, 1997; Lopez *et al.*, 2011). The transitions from the valence band (VB) to the intermediate band (IB) and from the IB to the conduction band (CB) result in the absorbance of the sub-bandgap energy photons, thus enabling IBSCs to achieve both high current and high voltage. To enable absorption from the VB into the empty states of the IB, the IB has to be partially occupied and from occupied states of the IB to the CB [811]. To preserve the high output voltage of the cell, the Fermi level is split into three separate quasi-Fermi levels (Luque *et al.*, 2012).

The theoretical limiting efficiency of IBSC is calculated to be 63%, derived at isotropic sunlight illumination and assuming the temperatures of the Sun and Earth to be 6000 K and 300 K, respectively (Luque and Marti, 1997). The maximum efficiency of a single-gap solar cell was 41% under the same conditions (Luque and Marti, 1997). The research on finding optimal sub-bandgap absorbers has been concentrated on alloys that naturally exhibit an IB and nanostructures, in particular, arrays of quantum dots (QDs) that form an IB (Luque *et al.*, 2012; Luque and Marti, 2011; Palacios *et al.*, 2008).

To exhibit three electronically isolated energy bands, the electronic band structure of highly mismatched semiconductor alloys can be tuned both experimentally and theoretically (Luque and Marti, 2011). By substituting a relatively small fraction of host atoms with an element of very different electronegativity, this can be achieved in the highly mismatched alloys. For example; III-V and II-VI alloys, in which group V and VI anions are replaced with the isovalent N and O, respectively (Yu *et al.*, 2003, 2006). The interaction between localized states associated with N or O atoms and the extended states of the host semiconductor matrix determine the electronic structure of such alloys. As a result, the conduction band gets subdivided into two sub-bands with clear non-parabolic dispersion relations, thus changing the optical and electrical properties of these alloys (Yu *et al.*, 2003). If the localized states lie well below the conduction band edge, only then a narrow lower band can be formed (Yu *et al.*, 2006). Consequently, by adding two new absorption edges, the absorption spectrum is modified, which can be tuned to lie within the spectrum of solar energy. Experimental examples include the IB formation within the bandgap of highly mismatched semiconductor alloys, for instance, $\text{Zn}_{1-y}\text{Mn}_y\text{O}_x\text{Te}_{1-x}$ and $\text{GaN}_x\text{As}_{1-x-y}\text{Py}$ (Yu *et al.*, 2003, 2006).

Spectral photoreflectance measurements detected the IB and its formation was attributed to band anti-crossing. Blocking layers were incorporated in order to obstruct electron tunneling between the IB and CB, and hence maintaining a high open-circuit voltage. From theoretical and computational perspectives, various calculations have been performed in the search for optimal IB materials. The most promising discovery of the quest has been $\text{V}_{0.25}\text{In}_{1.75}\text{S}_3$, because of its strong sub-bandgap absorption and the inherent partially filled IB. This implies that the IB is already partially filled without the necessity to rely on impurity doping, thus reducing densities and consequently lowering the absorption levels (Palacios *et al.*, 2008). Bulk IBSCs have so far exhibited efficiencies way below their promised potential, and the issue of finding the best candidate materials for this technology is extremely crucial if IBSC research is to be introduced to the mainstream solar cell generation.

Quantum dot IBSCs

From the confined states of QDs situated within the bandgap of a host semiconductor, an IB can also be formed. To enable the strong wave function overlap and the formation of minibands, QDs should be closely spaced and with high-quality interfaces. A high concentration of QDs is required to achieve strong absorption to and from IB. By engineering the parameters such as QD geometry (size and shape), inter-dot separation, and dot arrangement, IB position and width can be optimized for achieving the maximum efficiency (Shao *et al.*, 2007; Levy *et al.*, 2005; Laghumavarapu *et al.*, 2007). Typically, self-assembled (In, Ga) As QDs embedded in a GaAs matrix have been used as an IB (Luque *et al.*, 2012; Suraprapich *et al.*, 2006). Interestingly, features of IBSC operation have been demonstrated by some of these devices, and have achieved efficiencies over 18% (Luque *et al.*, 2012; Blokhin *et al.*, 2009).

Self-assembled QDs consist of approximately 10^4 – 10^6 atoms of a semiconductor such as (In, Ga) As embedded in another semiconductor matrix GaAs. They are synthesized by the Stranski–Krastanov (SK) growth mode, which uses the principle of natural lattice mismatch between the substrate and the deposited material (Shchukin and Bimberg, 1999; Shchukin *et al.*, 2003). The strain intensity in the layer as related to the misfit of the lattice constants, the temperature at which the growth occurs, and the growth rate are the contributing factors for the shape and average size of the QDs. The island emerges to the state of quasi-equilibrium in which they take the shape of pyramids or lenses formed on a thin wetting layer and then capped by the barrier material. The main advantages of the SK growth mode are a synthesis of defect-free QDs of small sizes, homogeneous sizes, and shapes of QDs, the formation of ordered uniform arrays of 3D coherent islands and quite convenient growth processes (Shchukin and Bimberg, 1999; Shchukin *et al.*, 2003). Their structural perfectness (absence of impurities, dislocations, and defects), the remarkable isolation from the environment and the ability to charge the system with a few electrons or holes (multiexcitons), have made them important in studying the arena of particle physics in confined spaces (Mlinar *et al.*, 2009; Mlinar and Zunger, 2009). In self-assembled QDs the multiexcitons survive and decay radiatively unlike colloidal QDs, where nonradiative decay channels rapidly destroy multiexcitons and cause blinking in photoluminescence (Efros and Rosen, 1997; Wang *et al.*, 2009). The self-assembled QDs are not influenced by the photo-corrosion and photostability of colloidal QDs, where QDs stability depends on the solution (e.g., it was found that CdS QDs in nonpolar solvent were significantly stable even under UV light exposition) (Sato *et al.*, 2007) (Fig. 1).

Some measure of homogeneity must exist between the successive quantum dot layers in order to create a mini-band. However, the number of QD layers are limited as a consequence of strain accumulation which in turn leads to the prevention information of quantum dots (Mlinar and Peeters, 2007a, 2006, 2007b). The strain symmetrization within the structure can help to lift the strain-induced limit of the number of QD layers. It was found that, even if the number of QD layers were increased, the absorption intensity between QD-confined electron states and the host CB remained weak because of their localized-to-delocalized character and the position of the IB within the matrix bandgap could not satisfy the suitable energetic locations for the IB (Popescu *et al.*, 2008).

Furthermore, the loss of output voltage at room temperature compared to reference solar cells without an IB has been one of the major challenges in the QD IBSC design (Luque *et al.*, 2012). The thermal escape of electrons from the IB to the CB (in addition to the tunneling of electrons from the IB to the CB) is the primary reason for the loss of voltage at room temperature (Luque *et al.*, 2012; Luque and Marti, 2011).

Fig. 1 Schematic diagram of a quantum dot intermediate band solar cell.

Thus, from a fundamental point of view, a better understanding of the nature of the IB (localized versus extended), and carrier relaxation processes is necessary for further exploration. From a purely technological perspective, the research for advanced fabrication techniques and more optimal materials (strain symmetrization and strong absorption between the IB and CB) is at the budding stage and has a lot of room for growth and development. As an insight into the sensitivity of the problem, significant elimination of output-voltage reduction was achieved by careful fabrication of InAs/GaAs IBSCs, potentially opening pathways for room temperature IBSCs (Bailey *et al.*, 2011).

Multiple exciton generation solar cells

The generation of more than one electron-hole pair (exciton) by absorption of one photon is known as Multiple exciton generations (MEG) or carrier multiplication (Nair *et al.*, 2011; Pijpers *et al.*, 2009; Beard *et al.*, 2010). Through a scattering process, known as impact ionization (the inverse of Auger recombination), high-energy photons, at least twice the bandgap energy, absorbed in a bulk semiconductor can generate one or more additional electron-hole pairs close to the bandgap energy (Conibeer, 2007; Nair *et al.*, 2011; Pijpers *et al.*, 2009; Beard *et al.*, 2010). Previously bulk Si, PbS, PbSe, Ge, InSb, etc., exhibited the impact ionization. Since the rate of impact ionization is much slower than the rate of radiative recombination at low electron energies (in visible and near IR spectrum) and the necessity to conserve momentum, this effect is inefficient in bulk concentration. In addition, as the required photon energies lie outside the solar spectrum (3.5 eV) the impact ionization in bulk is not useful for energy conversion purposes; for e.g., it requires approximately 7 eV photons to produce one extra carrier in silicon (Conibeer, 2007; Nair *et al.*, 2011; Semonin *et al.*, 2011).

Thus, it was proposed that MEG can be more efficient in semiconducting nanocrystals (Nozik, 2002; McGuire *et al.*, 2008). It was suggested that the relaxation dynamics of photogenerated carriers may be affected by quantization effects given the unique electronic structure properties of nanocrystals—atomic-like electronic structure and size-dependent bandgap energies, and thus lead to more efficient solar cells (Mlinar and Zunger, 2009; McGuire *et al.*, 2008). For example, hot carrier cooling rates of impact ionization could become competitive with the rate of carrier cooling (Conibeer, 2007; Ellingson *et al.*, 2005).

Numerous experiments have affirmed the existence of MEG in nanocrystals (although not undisputedly) by revealing that excitation of a semiconductor nanocrystal by a single, high-energy photon which may result in the formation of a few electron-hole pairs (Conibeer, 2007; Semonin *et al.*, 2011; Nozik, 2002, 2008; McGuire *et al.*, 2008; Ellingson *et al.*, 2005; Beard and Ellingson, 2008; Nair *et al.*, 2008; Ji *et al.*, 2009). The generation of multiple excitons from a single photon occurs on a very short time scale following photon absorption, where the efficiency increases with the energy of the photon (Fig. 2).

The number of excitons generated by absorption of a photon is defined by the efficiency " η " (Nair *et al.*, 2011; Beard *et al.*, 2010). Using the detailed balance model under the assumptions that all photons with energies above the bandgap were absorbed and those with energies less than the bandgap were not absorbed, that the only loss is the radiative recombination and that all photogenerated carriers are collected, the calculations are done (Beard *et al.*, 2010).

The ultrafast transient absorption spectroscopy is used to determine the number of electron-hole pairs produced per absorbed photon in a typical MEG experiment. Samples are irradiated with a low-intensity beam of high-energy photons, and the dynamics of multiexciton decay versus single exciton decay are measured. If a fast component with a lifetime same as that of a multiexciton lifetime is observed along with exciton decay, it is attributed to multiexciton. However, the existence of MEG artifacts can give 'false positive' signatures of MEG (Nair *et al.*, 2011). For example, due to the opening of nonradiative channels, the single exciton decay can acquire a fast component, e.g., electron or hole traps in a nanocrystal surface.

Furthermore, the role of quantum confinement for MEG has garnered certain disagreements and disputes. Interpretations ranging from those stating that the efficiency of MEG of the PbSe nanocrystal is about twice the efficiency observed in bulk PbSe to those stating that the advantage of nanocrystal MEG is only due to a possibly larger photovoltage because of the quantum confinement (Nair *et al.*, 2011; Beard *et al.*, 2010; Semonin *et al.*, 2011). Finally, there is also an issue of the impact that MEG can have on solar energy conversion.

Fig. 2 Development of a multiple exciton generation solar cell by using nanowires.

Theoretical studies related to the basic mechanisms of MEG gives ambiguous results. Theoretical models giving explanations of MEG ranging from a coherent superposition of single and multiple exciton states to excitations of virtual multiexciton states is still a matter of further delving into advanced research (Brown, 1970; Service, 2004). Additional constraints on the set of initial parameters are required in order to distinguish between different interpretations. The set of primary parameters include the coupling strength between excitons and multiexcitons, decay rates and density of states (Semonin *et al.*, 2011; Mlinar, 2012). This is yet to be addressed and resolved.

Hydrogen Economy

The predominantly identified renewable sources of energy available in nature, such as solar, wind, geothermal or tidal need to be converted to some other form of energy preferably electricity and transported from one place to other. Whereas, hydrogen needs to be generated and itself acts as both energy as well as a medium of transporting and storing energy. Hydrogen can be synthesized from renewable sources of energy and can be converted into electricity mainly using fuel cell technology with much ease. All these reasons attribute hydrogen, like any other fuel, to be considered a developing arena for energy studies and hence can claim to be the pivotal point of developing an economy.

One of the most promising and optimistic characteristic features of hydrogen is that the only product of its combustion is water. The production of hydrogen from renewable energies with its use in fuel cells combining with the utilization of the product of its combustion makes hydrogen a perfect candidate for leading the sustainable greener economy.

Hydrogen Production

Though hydrogen production, storage, and transformation into electricity have been ongoing since decades, we are still lacking efficient economical techniques to use this light gas in such a way that it makes the future hydrogen economy viable and relevant for commercialization. Being a vector than just a source, hydrogen is as clean as the way used to produce it. At present, the maximum production of hydrogen globally is done by steam reforming of natural gas (Service, 2004). Though this method has an efficiency ranging from 7%–80% but the production of CO₂ is a huge setback. Because of its inexpensive nature, it is speculated that this process will account for the bulk of hydrogen for the next 30–50 years until more cost-effective sustainable solutions are developed and implemented successfully.

Clean and sustainable electricity can be provided by renewable energy sources such as photovoltaic, wind, biomass, hydrothermal, and geothermal energies. However, these renewable energy sources, predominantly water electrolysis account for only around 5% of the commercial hydrogen production (Serrano *et al.*, 2009). In spite of the efficiency ranging higher than 70%, consumption of a significant amount of electricity, which inadvertently increases the costs is the prime reason for the absence of its commercialization.

The future of hydrogen production is its direct production from renewable sources avoiding electrical, heat and mechanical losses in a cost-effective manner. These include solar, thermal, wind energy, thermochemical cycles or biomass gasification and proton exchange membrane fuel cells. Apart from these, water splitting by Nano-photocatalysis one of the most promising alternatives for direct hydrogen generation via a renewable energy source in an economical and environmentally friendly manner (Züttel *et al.*, 2002). Unfortunately, according to the Royal Society of Chemistry report; new, clean and sustainable new pathways for the replacement of hydrocarbon-based hydrogen production processes are not expected before the year 2035.

Hydrogen Transport and Storage

Most of the presently available hydrogen storage systems are quite inefficient. For example, pressure vessels for the storage of hydrogen are not efficient enough as pressurized gas is bulky and heavy, low-temperature requirements of hydrogen storage in a

liquid state, the gravimetric storage density is low, etc. These disadvantages of transport and storage thus result in the loss of a great part of the energy produced. According to the Department of Energy of the United State of America, the threshold for a sustainable hydrogen storage system is a gravimetric storage density of 6.5 wt% and 62 kg H₂/m³ (Serrano *et al.*, 2009).

For the above-mentioned reasons, extensive research is being carried out to increase the capacity of existing hydrogen storage systems cumulatively with the aim to develop in parallel good hydrogen transport devices. Presently, hydrogen adsorption (chemisorption or physisorption) is considered to be one of the most efficient and sustainable ways to store a light gas like hydrogen.

The main drawback of Chemisorption techniques is binding hydrogen too tightly. Along with this, for discharge, the storage system must operate above ambient temperatures (>400K), while recharge is highly exothermic in nature. On the contrary, most physisorption techniques suffer from the reverse problem where significant adsorption can only be achieved at very low temperatures (<100K).

The use of activated carbon materials for hydrogen storage testing several carbon structures at cryogenic temperatures was suggested by Carpetis and Peschka (1980, 1976). Since then, these materials have been the subject of experimentation in the past decades. The wide pore size distribution and their inadequate pore size, which allows very small storage efficiency as most of the pores present higher sizes than those corresponding to hydrogen atoms or molecules are the main limitations (Schwartz and Amankwah, 1993; Dillon and Heben, 2001). Values of around 48 g H₂ per kg of carbon at 186°C under a pressure of 6 MPa have been reported (Schulz *et al.*, 1999). In both cases of chemisorption as well as physisorption, hydrogen adsorption kinetics can be improved by reducing the size of the adsorbing material to the nanosize range (Schwartz and Amankwah, 1993; Dillon and Heben, 2001; Schulz *et al.*, 1999).

Controlled pore size, shape and architecture and large surface areas, in many cases, in excess of 1000 m²/g are exhibited by mesoporous materials. In this manner, high adsorption capacities of hydrogen can be obtained by using nanomaterials that meet the criteria of high surface area, optimized pore size, and shape, high storage capacity, controlled desorption, and safety.

The physisorption of hydrogen on activated carbon with a controlled pore size distribution and the right surface chemistry is one of the novel alternatives to efficiently store hydrogen. Other alternate techniques to activate carbon involve various nanostructures such as carbon nanotubes, graphite nanofibers, and zeolites, to name a few (Züttel *et al.*, 2002; Schimmel *et al.*, 2003). Carbon nanotubes both multi-wall (MWCNT) and single-wall (SWCNT) carbon nanotubes have been suggested as potential candidates for efficient and economical hydrogen storage (Dresselhaus *et al.*, 1999; Hao *et al.*, 2003; Pinkerton *et al.*, 2000; Liu *et al.*, 2003; Shaijumon and Ramaprabhu, 2003).

Research findings of hydrogen adsorption by using SWCNT was first published dating back to 1998 and it was reported by Ye *et al.* (1999). The effect of the synthesis procedure by comparing laser-generated with those purified were analyzed by the authors. To describe these processes, various mechanisms of both physisorption and chemisorption of hydrogen on nanotubes have been suggested (Dai *et al.*, 2002; Gundiah *et al.*, 2003; Gao *et al.*, 2001; Zhang *et al.*, 2002). Nilsson *et al.* successfully reported the hydrogenation of single-walled carbon nanotubes (SWCNTs) using atomic hydrogen as the hydrogenation agent (Nikitin *et al.*, 2008). These authors have inferred that the nanotube diameter plays a key role in the maximal degree of nanotube hydrogenation. Nanotube-hydrogen complexes with close to 100% hydrogenation exist for approximately 2.0 nm diameter values and are stable at room temperature. This corresponds to 7 wt% of hydrogen storage capacity, which is higher than the one proposed as the goal for 2010 by the U.S. DOE (Serrano *et al.*, 2009). In a few years, other carbon materials, like graphite particles, have also been proposed as materials with great potential for hydrogen storage (Serrano *et al.*, 2009) (Fig. 3).

For hydrogen storage both at room temperature and cryogenic conditions and at different pressures, both zeolites and mesoporous materials with various nanostructures, have been tried as adsorbents. Their storage capacities being still too low

Fig. 3 (a) Structure of Carbon nanotubes. (b) Storage of hydrogen molecules in CNT.

(1.6 wt% at 77K at 36 bar in MCM-41), yet the inclusion of metal oxide dopants and incorporation of organic groups in the silica walls (organo-silicas) have a positive effect to increase the hydrogen storage capacity of these materials (Ramachandran *et al.*, 2007; Sheppard and Buckley, 2008; Jung *et al.*, 2006; García-Martínez *et al.*, 2007; Danilov *et al.*, 2008).

More efficient hydrogen adsorbents can be obtained with the aid of new mesoporous materials with hierarchical structures and controlled pore size. The use of biomolecules to produce bio-inspired porous silica is one of the most promising alternatives. For example, radically new hierarchical nanostructure with concentrically arranged pores assembled in a hexagonal array is produced by the addition of lecithin to a conventional synthesis of MCM-41 (García-Martínez *et al.*, 2007).

Noteworthy, Danilov *et al.* (2008) have recently synthesized porous carbon nanofibers proving its ability to efficiently store hydrogen. Thus, it can now be successfully treated as an alternative to hydride metals for its use in batteries. Nanofibers showed a surface area of 1700 m²/g after activation with KOH. Further modification and developments of the activated nanofibers enhance the discharge characteristics of the negative electrode. Moreover, through the modification of highly porous carbon nanofibers (surface area of 2000 m²/g) with Ni nanoparticles, nanomaterials with high hydrogen storage capacities were obtained by Kim and Park (2007).

Currently, a lot of attention is given to other hybrid materials based on coordination polymers, known as metal-organic frameworks (MOF) which are used as scaffolds for metals. These are being proposed as highly efficient hydrogen storage materials (Collins and Zho, 2007).

Metal or alloy hydrides are potential candidates to replace the more conventional methods for hydrogen storage (cryogenic liquid, compressed gas, and metal hydrides) taking into account both safety and cost. In these systems, the lattice of the metals or the alloys contain the hydrogen atoms thus achieving a storage capacity similar to the liquid hydrogen or pressurized hydrogen, chiefly depending on metal/alloy mass. Alloys like ZrV₂, Mg₂Ni, FeTi or LaNi₅ are used for storage purposes while in case of metal hydrides, MgH₂ also known as a high-temperature hydride with gravimetric storage of 0.07 kg of H₂/kg of metal also show true potential to successfully store hydrogen (Sherif *et al.*, 2005).

The three most crucial factors for the storage of hydrogen in metal or alloy hydrides are (1) Their capacity to store hydrogen, (2) the recycle and the reversible storage, and (3) hydrogen absorption/desorption kinetics. All of the above-mentioned reasons attribute to the alloy microstructure. In this light, nanostructured features in powder particles form have very distinct advantages. Some of the potential optimal materials for hydrogen storage in a few years' time can be envisioned in the Magnesium, aluminum or Mg-Al alloys either in the form of bulk materials with nanograins, or Mg-Ni alloys (nanocrystalline powders) (Serrano *et al.*, 2009). For example, Mg-Ni alloys not only have conventional sizes but their nanostructured interior confers efficient hydrogen absorption without the need for long activation treatment. It is also lightweight and relatively inexpensive material. The doping of metal hydrides with titanium nanoparticles is another feasible pathway but comes with certain drawbacks. Though sodium aluminum hydrides (NaAlH₄) doped with titanium nanoparticles can be treated as a sustainable and low-cost hydrogen transport and storage method, but the adversity is the limited market of Ti production hence inadequate development in the storage technique field.

The implementation of porous supports is a widely used technique to maintain the small size of nanoparticles. Usually, after the porous material has been prepared, the metal is loaded on its surface. A novel method of the incorporation of metal nanoparticles in high-quality mesoporous materials by functionalizing Pd nanoparticles with tri-alkoxysilane terminal groups has been developed recently (García-Martínez *et al.*, 2009). By copolymerization with tetra-alkoxysilanes in the presence of a surfactant, these modified nanoparticles are diffused into the porous structure of the silica. In this manner, the hydrogen adsorption performance of silica supported by palladium has been enhanced due to the obtaining of highly dispersed nanoparticles.

Boranes provide the citadel for the test of other chemical hydrogen storage materials. Recent studies show that the combination of boron and nitrogen can be treated as the potential solid-state hydrogen storage materials for onboard applications. A scaffold having 6–7 nm wide channels to hold ammonia borane (NH₃BH₃) in the nano-phase of silica mesoporous has been used by Brown *et al.* (2006). The hydrogen release kinetics at lower temperature was enhanced after the addition of saturated ammonia borane when embedded in a scaffold.

Fuel Cells

Hydrogen conversion has been the field of concentration of many researchers across the globe and over the years many new methods have been invented and developed. Both engines and fuel cells can burn hydrogen for generating energy. Like gasoline or natural gas, hydrogen can also undergo combustion in engines. Whereas fuel cells are electrochemical devices that basically transform the chemical energy of hydrogen into electrical energy. Fuel cells are among the most attractive and promising green technologies since electrochemical reactions are more controlled and efficient than combustion at generating energy (Sherif *et al.*, 2005; García-Martínez *et al.*, 2009). In a hydrogen fuel cell, hydrogen combines with oxygen in an electrochemical reaction (reverse of electrolysis) and produces direct electric current.

The various types of hydrogen fuel cells are classified on the basis of electrolytes as Polymer Electrolyte Membrane Fuel Cell (PEMFC), Phosphoric Acid Fuel Cell (PAFC), Alkaline Fuel Cell (AFC), Molten Carbonate Fuel Cell (MCFC) and Solid Oxide Fuel Cell (SOFC) (García-Martínez *et al.*, 2009).

The manufacturing costs are extremely high because of the expensive materials used for the manufacturing of electrodes' bipolar plates, the electrolytes, membranes, and catalysts where platinum is used. Hence, the cost of installation, as well as

production, is very high than the prevalent modes of electricity generation, fuel cells are being confined only to the laboratories. As a silver lining, the contribution of nanotechnology has considerably reduced the cost by improving efficiency even more. The huge number of research papers focused on nanotechnology applied to fuel cells that have been published in scientific journals since the last decade implies the extraordinary impact of this subject on the energy sector (Serrano *et al.*, 2009).

The automobile industry, power generation industries for both home and electronic applications have especially focused on works related to PEMFC for generation of zero-emission clean vehicles to tackle the alarming rate in which global warming is increasing. The clean and efficient green systems being a major solution to cut down the carbon dioxide and carbon monoxide content have always been a subject of high priority. But the two main obstacles that prevent its commercialization are the high cost of Pt/support electrodes and the low performance of the membrane, mainly at high temperatures.

The cost of the electrodes could be reduced significantly by decreasing the quantity as well as the durability of Pt catalyst needed for the application, is directly related to the support and catalytic influence. Carbon nanotubes-based electrodes for PEMFC fuel cells have been successfully synthesized by Wang *et al.* (2004) and Rajalakshmi *et al.* (2008). The authors found that instead of carbon powder, MWNT can be used as catalyst support thus allowing the reduction of the Pt used in comparison with the traditional PEMFC fuel cells by almost 2/3 times. For membrane electrode assemblies, higher performance and durability was observed while the electrodes showed higher thermal stability and higher catalytic activity. In his review "Novel catalyst support materials for PEM fuel cells: current status and future prospects", Shao *et al.* (2009) summarized the list of most feasible candidates for supporting the catalyst in the area of nanotechnology. For an alternative to the anode, tungsten carbides were proposed while diamond materials, in both conductive doped and nano-diamonds forms, were scouted for its use as a cathode. Carbon nanotubes, carbon nanofibers, mesoporous carbon and conductive oxides such as SnO_x/ITO , Ti_xO_y , TiO_2/ITO or WO_x are also projected to be used in commercial electrodes, in both cathode and anode. Doping is the main strategy for most of the mentioned in order to further escalate their application as supports of catalyst for the membrane fuel cells.

Synthesis of metallic nanostructured electrocatalysts with the aid of different self-assembled templates as structure-directing agents, capping agents are other alternatives that have been considered with importance. A silica-based template comprising of nanosized holes and bimetallic Pt–Ru nanowire networks, to be used as anodes of Direct Methanol Fuel Cells (DMFC) is experimented by Choi and Woo (2003). Chien and Jeng (2007) developed a new class of nano-catalysts based on three-dimensional Pt and Pt–Ru nano-structures with interconnected holes by using the same concept. Although they have been tested as a cathode (Pt) and anode (Pt–Ru) of specifically DMFC, these electrodes have potential applications on all membrane fuel cells in general. In a relatively newer study, using hexagonal self-assembled Ti/Si template, mesoporous Pt nanowire array has been prepared which shows potential applications in portable fuel cells (Zhong *et al.*, 2008).

One of the major contributions of nanotechnology with respect to the membrane performance is the use of nanoscale hydrophilic inorganic materials in electrolytes inorganic lithium salts. This has helped in improving the membrane's hydrogen ion conductivity at relatively high temperatures (the inorganic materials show a high affinity towards water and the salts function in the right temperature range). The use of capillary fuel cells instead of flat cell membranes is another growing alternative. The capillary cells are considerably cheaper than the flat cell membranes. Moreover, the closely packed construction results in approximately three to six times higher power density and allows to cut off the expenditure on the bipolar plates of the electrodes. In addition to this, the production of capillary fuel cells is fully automated and its miniature size makes it readily possible for portable applications. Additionally, the synthesis of nanoporous films of polybenzimidazole (PBI) doped with phosphoric acid has been mentioned by Mecerreyes *et al.* (2004). PBI doped with phosphoric acid already has its application as an electrolyte for methanol fuel cells (Wang *et al.*, 1995). With the introduction of nanoporosity in PBI, the increase in conductivity results in the betterment of the membrane performance as well. To obtain an enhanced performance mainly at high temperatures, the conventional Nafion membrane has been modified with titanium and tin dioxide nanoparticles by Abbaraju *et al.* (2008). Deposition of silica nanoparticles on sulfonated poly(aryl ether sulfone) has resulted in the fabrication of nanostructured membranes with special attention towards proton and ethanol fuel cells (Magno de Carvalho *et al.*, 2008).

Parallely, advances in SOFC are also in process with a heavy reliance on nanotechnology. Ignatiev *et al.* (2008) fabricated a nanoengineered SOFC with ultra-thin films supported by metallic foils. There was a remarkable decrease in the operating temperature in comparison with traditional SOFC. The efficiency of these nanoengineered and nano-structured fuel cells was found out to be above 50% with a maximum power density of 140 mW/cm² at 575°C.

Rechargeable Batteries

The rechargeable lithium battery is the prime focus of the research in this sector presently. In comparison to the aqueous batteries, the Li-ion batteries have shown an increase ranging between 100%–150% on the storage capability of energy per unit weight and volume. The major limitations are related to low energy and power density, a large change in volume on reaction, safety and cost of manufacture. The aforesaid shortcomings are tackled by the infusion of nanotechnology into the field of rechargeable batteries.

A tin-based anode nanobattery, trade named "Nexelion" has been commercialized by Sony Corporation. For the first time, the graphite electrode in the battery was replaced by a nano-alloy (Serrano *et al.*, 2009; Inoue, 2006). In the same line, Toshiba Corporation's claim of the new nanobattery that can recharge 80% of a battery's energy capacity in only 1 min has been a matter of great discussion. According to the company's model, this is approximately 60 times faster than the typical lithium-ion batteries and on a further note combines this fast recharge time with performance-boosting improvements in energy density.

Introduction of nanoparticles of alumina, silicon or zirconium to non-aqueous liquid electrolytes have increased the conductivity of the electrolyte up to six times. Solid state electrolytes, solid polymer electrolytes (SPE) have been the focus of most of the efforts. Since PEO is safe, green and can make flexible films, Poly(ethylene oxide)-based (PEO-based) SPE gathered most attention. As polymers have a low conductivity in room temperatures and are not mechanically stable enough, nanocomposite polymer electrolytes act as the best replacement in the fabrication of highly efficient, safe and green batteries. For instance, the electrical conductivity of the polymer electrolytes at room temperature increased by 10–100 times compared to the corresponding undispersed SPE system due to the inclusion of ceramic nanomaterials as separators. Out of TiO_2 , Al_2O_3 and SiO_2 and S-ZrO₂ (sulfate-promoted superacid zirconia) used for this purpose, the incorporation of S-ZrO₂ led to the best performance (Bruce *et al.*, 2008; Agrawal and Pandey, 2008; Whittingham, 2008; Patil *et al.*, 2008).

The substitution of LiC_6 electrode, with storage capacities of 340 mAh/g, by graphite nanoparticles and carbon nanotubes, is an important replacement in the structure of anode of the lithium batteries. Further replacement by nanosized metal oxides (i.e., titanium, aluminum, vanadium, cobalt, tin as well as silicon oxides) mostly in the form of nanotubes and nanowires have brought a solution to both depositions as well as some safety problems (Nam *et al.*, 2006; Park *et al.*, 2007; Chan *et al.*, 2007). For instance, the silicon nanowire synthesis harbored to the substrate act as a current collector to obtain a charge capacity of ca. 3000 mAh/g during 10 cycles after the first one, losing around one-third of capacity in the first cycle as inferred by Chan *et al.* (2008).

To increase the life cycle of nanocomposites through the reduction of volume change caused during the formation of the alloy, nano-scaled metal alloy composites are employed. For example, out of all Lithium alloys, Li_4Si has the highest gravimetric energy density, 4200 mAh/g, and the change in volume during alloy formation is around 400%. With this perspective, the most potential applications can be accounted for as: (i) thenano-architected anode construction in a variety of nanoforms (ii) deposition of nanoparticles on nanostructured copper roads (i.e., Ni_3Sn_4 for $\text{Li}_{4.4}\text{Sn}$) by displacement reactions to fabricate intermetallic electrodes as nanoparticles and (iii) the applications of nanostructured alloys in amorphous forms (titanium, vanadium, chrome or cobalt in amorphous tin phase) (Green *et al.*, 2003; Taberna *et al.*, 2006; Timmons and Dahn, 2007; Hassoun *et al.*, 2007).

For cathode reconstruction with the help of nanotechnology, it has been found that main suitable candidates for both environmental and economic reasons are manganese oxides, LiMn_2O_4 in bulk and vanadium oxides. Since nanoparticles are required to be coated to avoid sintering and increasing conductivity, they are not preferred. In this case, nanotubes and nanowires of vanadium oxide or lithium intercalation host including manganese oxides have shown a good performance. The very fact that storage and rate capability of V_2O_5 depends on the morphology and nanocables showed better performance than nanotubes or nanorods was proven by Wang *et al.* (2006). Other architectures involve fabrication of ordered mesoporous cathodes (which could arrange the electrolyte inside the pores) by using mesoporous silica templates as well as liquid crystalline electrolytes notably increase the battery performance LiMn_2O_4 , LiCoO_2 or NiOOH are to name a few recently studied mesoporous cathodes.

Wind Energy

The other booming energy sector of this era is the wind energy sector. The main governing principle behind a wind energy system (i.e., wind turbine) is to convert the kinetic (moving) energy of the wind into mechanical or electrical energy which is then used for practical purposes. Since wind energy does not deal with the combustion of any sort, hence it is environment-friendly and can be treated as green energy. Moreover, wind energy being a natural resource which is renewable in nature, it serves as a long-term solution to the current energy crisis. In comparison to the other power resources, the effects of wind energy on the environment are generally less adverse.

To fully utilize a wind power plant to its perfect effect, the wind speed should be at least 13–15 m/s. For comparatively smaller wind power, the wind speed can be approximately 10 m/s. The efficiency of wind power plants varies from 30% to 60% on average since wind speed is not uniform throughout the day. The energy generated by a wind turbine is directly proportional to the square of its blade length (Mostafaeipour *et al.*, 2011; Burton *et al.*, 2001).

Nano-composite materials exhibit extraordinary strength to weight and stiffness to weight ratios. Therefore, the construction of longer, stronger blades is recommended. The reduction of energy losses caused by some tribological issues like micro-pitting, wear, scuffing and spalling in gearboxes can be attributed as one of the effects of incorporating nanotechnology. Hence the wind turbine efficiency increases significantly. Some promising solutions to counter the energy loss problems are nano-lubricants and low-friction coatings (Sherif *et al.*, 2005). Using a sliding contact linear reciprocating rig to estimate the wear behavior and friction of a boron nitride-based surface and nano-particle lubricant additives for wind turbine gearbox applications were experimentally calculated by Greco *et al.* (Dalili *et al.*, 2009). The studies were mainly focused to adjust to severe operating conditions and mitigate surface originated failure.

To form a wear protective tribo-film, nano-colloidal boron nitride based lubricant additives are considered as an alternative technology to react with the borided surface. The boro-carburized surface showed much less wearing track and even the surface within the wear track was smoother than the surrounding surface. The conclusion was that a wear resistive tribo-film was formed by a chemical reaction due to the infusion of nano-colloidal boron nitride additive in commercial gear oil. Moreover, the mechanical properties of the surface layer were improved by the borided surfaces thus leading to increased wear resistance (Greco *et al.*, 2011).

Geothermal Energy

The thermal energy originating from the earth's crust is termed as Geothermal Energy. This varies between 5 and 10 km in length. The temperature is very high in the depths of the earth's crust. So, to cool the pipes which were exposed to the extremely high temperatures, nanofluids can be used as a cooling-agents to cool the pipes. Sensors and electronics in drilling machines which operate under high friction and high-temperature conditions are also cooled by using these nanofluids.

The sources of geothermal energy are classified in three main categories with respect to the measured temperature as low ($<100^{\circ}\text{C}$), medium ($100\text{--}150^{\circ}\text{C}$) and high temperature ($>150^{\circ}\text{C}$). A ground heat exchanger is mainly employed for the extraction of the energy (Kalagirou, 2005). The driving force for the conduction of thermal energy is the geothermal gradient. A geothermal gradient is defined as the difference in temperature between the core of the earth and its surface. On the other hand, the extraction energy from the core of the earth until the processing of it into a power plant system can be done by nanofluids as well. Thus, a large amount of work energy can be generated with the aid of nanotechnology in the geothermal sector as well.

Since the last few decades, geothermal energy has gained wide popularity for its varied applications. Household heating and electricity generation in small industries are the primary applications for the geothermal energy procured from the natural reserves. It has been reported that more than 72 countries have already started proper usage of geothermal energy. Almost 93% of the homes in Iceland are heated by geothermal energy, thus making it a global leader in the geothermal energy sector. Inevitably, Iceland is saving over 100 million dollars annually by substituting oil imports with geothermal energy. Since the generation of geothermal energy and its conversion to heat and electrical energy does not require any combustion, Iceland has also emerged as one of the cleanest countries thus making an exemplary difference in the global sustainable economy (Pahl, 2007).

As geothermal power plants can operate 24 h per day unlike tidal, solar, wind, it has been identified as a promising candidate to replace fossil fuels. With the current base-load capacity, the global potential for geothermal power generation is roughly estimated to be 85 GW within the next 30 years. But geothermal power is highly topography centric and the reserve is not distributed uniformly over the surface of the earth. Hence making it accessible in mainly the United States, Central America, East Africa, Iceland, Indonesia, and the Philippines (Hussein, 2015).

However, the major challenge encountered in the procurement of geothermal energy is the necessity for deep borings. The drilling is identified as the major reason for the triggered tremors or earthquakes in geographically weak areas. The research on nanofluids which is capable of encapsulating energy of higher orders in comparison to the other thermal fluids has opened up a portal of future research possibilities to counter the threat of digging deep borings (Ganguly *et al.*, 2012).

Conclusion

To cater to the world's increasing demand for energy, alternative forms of energy is slowly and steadily reaching the mainstream energy sector due to their wide availability, renewable nature and significant compatibility with the environment. The limitations of sustainability have led researchers and scientists to delve into studies of nanotechnology which promise optimistic ways to troubleshoot the major concerns.

The solar economy, which dominates the renewable energy sector has not achieved the expected efficiency or the economic feasibility with the traditional silicon based solar cells. Material science in the form of nanotechnology has been inculcated in the solar energy sector with the objective of increasing efficiency, ease of manufacturing thus broadening the acceptance in the market. The PV solar cells or the first-generation solar cells have experienced a rise in controlling the band-gap and interchangeability with the aid of quantum dots which have a close to 40% of the total efficiency of the present solar cells. Moreover, the inclusion of a vertically aligned nanowire array deal with the problems of exciton diffusion.

Hydrogen, on the other hand, has caught the attention of the scientists for its use as clean energy as it leaves only water as the by-product after combustion. But the generation and the storage of this green energy has faced some serious challenges with the prevalent techniques. Thanks to nanotechnology, single-walled and multiple-walled carbon nanotubes with the principles of physisorption and chemisorption as well as mesoporous materials with hierarchical structures and controlled pore size are gaining popularity for potential ways to store hydrogen. The development of graphene based membranes, as well as carbon nanotubes, carbon nanofibers, mesoporous carbon and conductive oxides for substituting the expensive platinum electrodes, aim to bring down the manufacturing costs of fuel cells with the aid of nanotechnology.

The inclusion of nanocomposites, nano-solvent coatings on the walls of the wind turbine blades are proposedly helping to reduce the friction and increase efficiency. Nanofluid which can function as both thermal fluid and coolant is emerging as a suitable alternative to the present drilling methods for procuring geothermal energy. The review discusses the various proposed as well as implemented ways by which nanotechnology can make a difference to the prevalent renewable energy sector and scientists in unanimity believe that these are just glimpses of what nanoscience and nanotechnology are actually capable of achieving.

Optimal Operation of Renewable Distributed Generators (DGs) and its Environmental Benefits

Chandan K Chanda and Dipanjan Bose, Indian Institute of Engineering Science and Technology, Shibpur, India

Introduction

Renewable distributed generation is expected to become more important in the future generation system. Renewable Distributed electricity generation, is a kind of new concept in the literature of pricing about markets of electricity, although the idea behind this is not new at all. At early days when there was no AC generation, DC distributed generation was ruling the electricity markets. The first power plants only supplied electricity to near customers of the generating plant. The first grid established were DC based, and therefore, the supply voltage was limited, as was the distance that could be used between generator and consumer. Balancing demand and supply was partially done using local storage, i.e., batteries, which could be directly coupled to the DC grid. Along with distributed generation, local storage is also returning to the scene. Later, technological evolutions, such as the emergence of AC grids (Thanks to scientist Tesla), allowed for electricity to be transported over longer distances lead to an increase in the power output of the generation units. All this resulted in increased convenience and lower per unit costs and massive electricity systems were constructed, consisting of huge transmission and distribution grids and large generation plants. Balancing demand and supply was done by the averaging effect of the combination of large amounts of instantaneous variation of loads. Reliability and security of supply was increased as the failure of one power plant was compensated by the other power plants in the interconnected system. In fact this interconnected high voltage system made the economy of scale in generation possible. In the last decade, sharp technological innovations and a changing economic and regulatory environment have resulted in a renewed interest for distributed generation. This is confirmed by the IEA (2002), who lists five major factors that contribute to this evolution, i.e., developments in distributed generation technologies, constraints on the construction of new transmission lines, increased customer demand for highly reliable electricity, the electricity market liberalization and concerns about global climate change.

Here we present general ideas of renewable distributed generation. Definition and different technologies, which are allowed dispersed generation of electricity, are discussed in Part-1. The important characteristics of every technology are summarized in Table 1. Then we discuss the major benefits that are offered by the use of distributed generation. Part-3 focuses on the major issues that are raised in the distributed generation literature. This illustrates that many of the benefits and issues depend on the renewable distributed generation technology used. In Part-4 the resilience of such networks is being shown and one flowchart (Fig. 1) is being prepared for the intentional cyber-attacks to the network. Part-5 then tries to show the environmental aspects of dispersed generation. The impacts due to the renewable distributed generation is summarized in Table 2. Finally, Part-6 is the conclusive part of the discussion.

Distributed Generation: Brief Description

In the previous sections, renewable distributed generation was loosely defined as small-scale electricity generation. The different technologies that can be used for it were listed in Table 1. A short survey of the literature shows that there is no consensus. This is confirmed by CIRED (1999), on the basis of a questionnaire submitted to the member countries. Some countries define distributed generation on the basis of the voltage level, whereas others start from the principle that distributed generation is connected to circuits from which consumer loads are supplied directly. Other countries define distributed generation as having some basic characteristic. The European Renewable Energy Study (TERES), commissioned by the European Union (EU) to examine the feasibility of EU CO₂-reduction goals and the EU renewable energy targets, found that around 60% of the renewable energy potential that can be utilized until 2010 can be categorized as decentralized power sources. Thus, generation units built by the transmission grid operator as a substitute for grid expansion and that have measures implemented for dispatching are not considered to be distributed generation according to this philosophy.

The IEEE defines distributed generation as the generation of electricity by facilities that are sufficiently smaller than central generating plants so as to allow interconnection at nearly any point in a power system 10. On the basis of the definitions surveyed in their paper, Dondi *et al.* (2002) define distributed generation as a small source of electric power generation or storage (typically ranging from less than a kW to tens of MW) that is not a part of a large central power system and is located close to the load. These authors also include storage facilities in the definition of distributed generation, which is not conventional. Furthermore, their definition emphasizes the relatively small scale of the generation units as opposed to CIRED and CIGRE. Chambers (2001) also defines distributed generation as relatively small generation units of 30 MW or less. These units are sited at or near customer sites to meet specific customer needs, to support economic operation of the distribution grid, or both.

With the exception of the CIGRE definition, all definitions assume that distributed generation units are connected to the distribution network. This is also the case for the definition used by IEA (2002), which sees distributed generation as units

Table 1 Different technologies of renewable distributed generations

Name	Basic information	Generation range ^a	Efficiency of electric conversion ^b	Renewable sources ^b	Application ^b	Remarks
Fuel cell	Device which converts chemical energy into electrical energy	50 kW–2 MW	35%–55%	Methanol (CH ₃ OH) Natural gas Reforming of CH ₄ to H ₂ leads to decreased efficiency	IC engines or dc batteries.	If the H ₂ comes out from electrolysis of water. energy, it reduces CO ₂ and CH ₄ gases emission
Photovoltaic	Generates no heat and produces electricity from solar radiation	1–5 kW Every range possible when using more cells	25%–30%	Sun	Home appliances application and a few commercial applications Isolated-grid applications Developing countries	Non predictable output
Wind	Converts wind energy to electrical energy by wind-turbines	Every range possible when using more windmill	50%–60%	Wind	Household In a few scale applications	Non predictable output
Hydro	Natural resource of river water	100 kW–30 MW	80%–85%	Water	Household and smallcommercial applications Off-grid/grid applications Countries which are developing Small applications in houses Household and small industrial applications	A very high value of output; capacity factor ~80%–85% in Western Europe
Biomass	Biofuel, Waste management system		30%–40%	Biological waste	Smallcommercial applications Developing countries	
Geothermal energy	Thermal energy of Earth		2%–5%	Earth temperature	Smallcommercial applications Developing countries	
Other	renewables	OTEC (Ocean thermal energy conversions)		Not applicable	Temperature difference between cooled water and warm tropical surface waters.	Smallcommercial applications
Developing countries

Fig. 1 Block diagram of the attack resilient distributed generation.

producing power on a customer's site or within local distribution utilities, and supplying power directly to the local distribution network. The Electric Power Research Institute defines distributed generation as generation from 'a few kilowatts up to 50 MW'.

IEA, however, makes no reference to the generation capacity level as opposed to all other definitions. It should be clear by now, that many definitions of distributed generation exist, allowing for a wide range of possible generation schemes. Some definitions allow for the inclusion of larger-scale cogeneration units or large wind farms connected to the transmission grid, others put the focus on small-scale generation units connected to the distribution grid. All these definitions suggest that at least the small-scale generation units connected to the distribution grid are to be considered as part of distributed generation. Moreover, generation units installed close to the load or at the customer side of the meter are also commonly identified as distributed generation. This latter criterion partially overlaps with the first, as most of the generation units on customer sites are also connected to the distribution grid. However, it also includes somewhat larger generation units, installed on customer sites, but connected to the transmission grid. This leads to the definition proposed by Ackermann *et al.* (2001), who define distributed generation in terms of connection and location rather than in terms of generation capacity. They define a distributed generation source as an electric power generation source connected directly to the distribution network or on the customer side of the meter. We favor this definition, even though it is rather broad. Indeed, it puts no limit on technology or capacity (relative: in % of the country) of the potential distributed generation applications.

Therefore, some additional criteria can be helpful and necessary to further narrow the definition in function of the research question that is tackled. The following paragraphs list a (no exhaustive) number of these criteria along with a short discussion. Voltage level at grid connection (transmission/distribution) Although some authors allow distributed generation to be connected to the transmission grid, most authors see distributed generation as being connected to the distribution network, either on the distribution or on the consumers' side of the meter. In all cases, the idea is accepted that distributed generation should be located closely to the load. The problem is that a distinction between distribution and transmission grid, based on voltage levels, is not always useful, because of the existing overlap of these voltage levels for lines in the transmission and distribution grid. Moreover, the 'legal' voltage level that distinguishes distribution from transmission can differ from region to region. Therefore, it is best not to use the voltage level as an element of the definition of distributed generation. It would be more appropriate to use the concepts 'distribution network' (usually radial) and 'transmission network' (usually meshed) and to refer to the legal definition of these networks as they are used in the country under consideration.

Different Technologies of Distributed Generation

Here we presented in a tabular form of the different technologies which can be implemented for renewable distributed electricity generation. All the technologies are not analyzed in great detail. From this discussion the advantages and disadvantages of dispersed generation are given below in Table 1.

Utility of Renewable Distributed Generation

It was mentioned in the above section, the IEA identifies five major aspects which are contributing to the interest in dispersed generation. We describes five factors which can be further more reduced to 2 main actuating forces, i.e., open electricity market and concerns about environment. We doubt that decentralized generation is adept of intermitted, and certainly maintain, the employment of new transmission lines. Reliability being the third most important element and resiliency must be accounted for the hazards like natural disaster or cyber terrorism in constructing the plants of renewable generations.

The De-Regulation of Markets for Electricity

An increment in interest of electricity suppliers in renewable distributed generation as market suppliers make it as a tool which could help them to create niches in an open market. Customers will look into in such a market; customers will look for the electricity service best suited for them. Different customers attach different weights to features of electricity supply, and distributed generation technologies can help electricity suppliers to supply to the electricity customers the type of electricity service they prefer. In short, distributed generation allows players in the electricity sector to respond in a flexible way to changing market conditions. Some major examples are discussed below.

In open markets, it is important to adapt to the changing economic environment in the most flexible way. Distributed generation technologies generally provide this flexibility because of their small sizes and the short construction lead times compared to most types of larger central power plants. According to the IEA (2002), the value of their flexibility is probably understated when economic assessments of distributed generation are made³. It should be stated that the lead time reduction is not always that evident. Public resistance to for instance wind energy and use of landfill gasses may be very high.

Backup Capacity

Many distributed generation technologies are indeed flexible in several respects: operation, size and expandability. For example, making use of distributed generation allows reacting in a flexible way to electricity price evolutions. Distributed generation then serves as a hedge against these price fluctuations.

Apparently, the demand for distributed generation is mainly driven by price volatility, i.e., using distributed generation for continuous use or for peaking use (peak shaving). In the market demand for distributed generation is, for the moment, driven by heat applications, introduction of renewables and by potential efficiency improvements. These will be discussed below.

High Installation Cost

The IEA (2002) and many others claim that one of the major remaining issues is the relatively high capital costs per kW installed power compared to large central plants. Moreover, differences in capital costs between the different distributed generation technologies are also quite large, ranging from €1000 per kW to over €20,000 per kW for solar, wind and fuel cells, respectively.

More Choice Between Renewable Sources

An increasing share of renewable distributed generation in the installed generation capacity, implies more choice between renewable sources. Given that most distributed generation technologies are (primarily) based on solar and wind. We expect an increased demand for and dependency on solar. The importance of this argument crucially depends on the market share of distributed generation in the total generation capacity, but also, for example, on the amount of cogeneration that is installed, as this will lead to increased pricing but lower environmental pollution.

Another claim is that the primary fuel supply for renewable distributed generation applications will usually be less costly than that for central coal based generation. In the demand for renewable energy sources that can be used to obtain some more efficient technologies.

Economic Efficiency

Economic efficiency refers to the principle that wasting valuable resources should be avoided. The extent to which distributed generation is integrated efficiently in the electricity market things upon the market structure, the market operation and upon pricing. In many countries, the structure of the electricity market is revised through the de-regulation process. The final market structure will have an influence on the penetration potential of renewable distributed generation. An economically efficient deployment would require an open scope of the retail market in the sense that electricity customers then have the option to generate their own electricity in response to price if a dispatchable DG technology is used. If only wholesale market liberalization is achieved, electricity customers would essentially be faced with a monopolist at the distribution level. This monopolist can easily discourage the installation of distributed generation, for example by charging high prices for ancillary services or by offering very low prices for distributed power supplied to the grid. Clearly, the regulator could play a role here, for example by fixing (minimum) buy-back prices, but these prices risk to be set at inefficient levels such that either too much or too little distributed generation capacity is installed. Liberalization at the retail level is not a sufficient condition for non-discriminatory access of distributed generation to the grid. Grid operators that own generation capacity also have an incentive to discriminate against distributed generation. A separation of generation and distribution transport activities is necessary to remove this incentive. In the latter case, some potential benefits mentioned in the next part will be more difficult to realize (renewable distributed generation as an alternative to grid expansion).

Often, the liberalization of the electricity market has led to the introduction of spot markets for electricity. These markets play an important role in the balancing of supply and demand. Retailers unable to meet their forecasted output or demand must turn

to the balancing market where they pay high prices for their imbalances. Clearly, distributed generators are adversely affected by this evolution because they typically have difficulties to forecast their output (renewable). In principle, prices should reflect underlying demand and supply conditions, which can vary overtime and place. In practice, electricity prices are rarely sensitive to location, except when there are important technical reasons for price differences found in the grid, and in many cases they are also not sensitive to time, except for corrections for day/night or weekend and seasonal. Pricing mechanisms based on varying demand and supply conditions will encourage an efficient use and deployment of (distributed) generation. The use of time based pricing schemes is increasing, but location based pricing schemes are apparently more difficult to implement.

Cheap Renewable Fuel Opportunities

Setting up renewable distributed generation allows the exploitation of cheap fuel opportunities. For example, in the proximity of landfills, distributed generation units could burn landfill gasses. Also, other locally available biomass may be used. In short, the decentralization of the electricity market and increased environmental concerns both induce an enhanced interest in distributed generation applications and thus also in innovations in the appropriate technologies. However, the economic as well as technical challenge will be to optimally integrate this increasing number of small generation units in an electricity system that up to now has been very centralized and integrated and planned.

Geographical Diversities

The modular nature of renewable energy technologies, such as wind turbines and solar photovoltaic (PV), allows greater geographical diversification of energy supplies compared to conventional power generation systems, which deliver power from a concentrated point or central location. This increased regional diversification reduces the vulnerability of the energy supply to cause damage from a single event or a single critical location, which increases overall energy system resilience.

Micro Grids

Microgrids capable of islanding based on renewable distributed generation (DG) can disconnect from the central grid during a major climate event to allow energy to be diverted to critical loads. This allows utilities flexibility in restoring generation stations, responding to critical outages, and shutting down systems before a major event to prevent damage. Islanded DG systems ensure consumers have access to power during long-term power outages that severely impact central grid systems, which can occur after major natural disasters.

Strategy

New Jersey had more than 1000 megawatts (MW) of installed solar capacity when “Hurricane Sandy” hit the Northeast United States. However, only 2 solar PV systems provided power in the days following the “hurricane” (Stout and Hotchkiss, 2017). At the time, a combination of interconnection strategy and a lack of dynamic controls or transfer switches prevented the islanding of systems. Without appropriate strategy and codes, the installed DG capacity could not do a little to aid resiliency. Selected locations to enhance resiliency through DG may adopt appropriate policy on interconnection and islanding to realize the full benefits of these energy generation systems.

Redundancy

Redundancy is critical to most operations, but is essential for resiliency. The increased stress on infrastructure systems as a result of changing climate or other threats has the potential to increase the likelihood of failure of one or more parts of a system. Communities served by only one power line has limited resilience. Increasing supplies, routes, or incorporating redundancy to overall systems will reduce the risks of those systems. In an analysis conducted for a community in New England, it is determined that pairing renewable energy and energy storage technologies with conventional backup power systems increased the number of days a system could operate without grid connection.

Generation Capacity (MW)

One of the most obvious criteria would be the generation capacity of the units installed. However, the short survey of definitions illustrated that there is no agreement on maximum generation capacity levels and the conclusion is that generation capacity is not a relevant criterion. The major argument is that the maximum distributed generation capacity that can be connected to the distribution grid is a function of the capacity of the distribution grid itself. Because this latter capacity can differ widely, it is not possible to include it as an element of the definition of distributed generation. However, this does not imply that the capacity of

the connected generation units is not important. Thus, a narrowed definition of distributed generation could, among other things, be based on the generation capacity criterion. Services supplied Generation units should by definition at least supply active power in order to be considered as distributed generation. The supply of reactive power and/or other ancillary services is possible and may represent an added value, but is not necessary.

Generation Technology

In some cases, it can be helpful to clarify the general definition of distributed generation by summing up the generation technologies that are taken into account. It would however be difficult to use this approach to come to a definition because the availability of (scalable) technologies and of capacities, especially in the field of renewable, differs between countries. Also conventional systems such as gas turbines are available over wide ranges (a few kW to 500 MW). Sometimes, it is claimed that distributed generation technologies should be renewable. On the other hand, not all plants using 'green' technologies are supplying distributed generation. This would, for example, depend on the plant size or on the grid to which the installation is connected (transmission or distribution).

Mode of Operation

Ackermann *et al.* (2001) had not taken account the mode of operation as an important element in the definition of small scale generation. The corrected view, at that time must be considered more problems regarding distributed generation, especially the fact on that these units are beyond control from grid operations. Converging to the definition, the criterion, mode of operation is appropriately used. Within the same distribution network area, power generation and consumption may take place simultaneously.

Benefits of Renewable Distributed Generation

Several benefits of introducing renewable distributed generation in consonance with existing distributed networks are economical, environment-friendly and many technical implications are interrelated. Hence, it is classified the benefits into three groups – technical, environmental and economical.

The major technical benefits are:

- Line losses will be reduced;
- Improvement of Voltage profile;
- Overall energy efficiency will be increased;
- Enhancement of system reliability and security;
- Power quality will be improved.

The major environmental benefits are:

- Emissions of pollutants will be reduced;
- Due to environmental improvement health care costs will be reduced.

The major economic benefits are:

- For up-gradation of facilities investments will be very high;
- Productivity enhancement;
- Due to increment in overall efficiency fuel costs will be reduced;
- Operating costs will be very much less;
- Security for critical loads will be increased.

An approach to technical benefits of introducing renewable DGs can accrue in one of two broad categories:

- (1) Improvement of a certain aspect such as reliability, power quality, voltage profile, resiliency, environmental issues, healthcare assessment etc.
- (2) Reduce of an aspect such as emissions, congestion, pollution, line losses etc.

Resilient Operation of Power Network Having Renewable Distributed Generation

By the looming decentralized environment confront by the electric industry, many renewable distributed generation options are attaining its great economical viabilities by the help of some advancement in technologies. Magnitudes of recent natural hazards have created a new situation for the power industry. In below they are presented.

- Open market of the power generation industry and the subsequent breakup of the hierarchy of that system.
- Constructing new power network over the environmental ground opposes by the public.
- Electric power generation impacts on environment, makes the people aware.
- In some parts of the country the demand in electric power increases rapidly.
- Significant advancement in various generation technologies which are much more eco-friendly such that wind to electricity generation, hydro generation, solar generation, fuel cell, biomass and ocean thermal electricity conversion than conventional oil, coal and gas-fired plants.
- Increasing desires of public to promote green or eco friendly technologies which are based on renewable energy sources.
- Awareness for these opportunities of distributed generation for enhancement of the resiliency on power supply, especially to highly important loads, by promoting mini and micro grids in case of emergencies and/or terrorist attacks, cyber-attacks and/or embargoes of energy supplies.

All these factors discussed above have incremented interest for the development and usefulness of renewable DGs. There are various technologies which utilizes renewable energy resources. Hence forth the individual that show promise for DG applications are: wind energy, biomass systems, photovoltaic, solar-thermal-electric systems, Fuel cells, and geothermal systems. The DGs can range from a few kilowatts up to 300 MW. Capacity credit, energy cost saving and energy value are quantified and evaluated as the important part of DGs.

Distributed Generation Considering Attack Resilient Power Flow

Discussing attack resilient power flow over the natural hazards and cyber-terrorism to quantifying some technical benefits. The block diagram is shown below in [Fig. 1](#).

Resiliency: A Protective Approach to Power System

Globally it is initiated by the governments to be adopted and implemented various actions regarding climate change and reducing global warming effects. By adapting some resilient actions with the renewable distributed generations to overcome environmental degradation as well as natural hazards and intentional cyber attacks. Analytical and technical support provided all over the world for important lessons on resilience associated with renewable power generation. Renewable distributed energy generation is a huge factor in development of resilience with green energy technologies and its solutions. There are some key points discussed below.

- Power sector vulnerabilities and potential hazards may impede the provision of the energy services necessary to achieve economic growth and development goals.
- Planning for resilience can help communities avoid and recover from potential threats and vulnerabilities to the power sector.
- Renewable energy-based generation can enhance resilience due to its modular nature, ability to operate in severe weather when designed to do so, and lack of fossil fuel requirements.
- Decision makers may consider enacting policies that enable resilience strategies; coordinate their implementation; and evaluate their effectiveness on a regular basis.

The Resilience Roadmap is to be prepared for federal, state, and local entities to effectively convince at the regional level for adaptable and holistic planning. A step-by-step process offers guidance, exercises and aggregated data lists to support decision makers. The descriptions of data and hemorrhages report during any natural calamity or at any cyber-terrorism.

Methods Used to Designing the Resilience Roadmap and Some Case Study

From the zero level, the ability of recovering the stress from the application and retains its original state very quickly is termed as resilience. Increment in resilience means it reduces vulnerabilities and various threats to the power system having renewable distributed generations. In consonance with the effects of natural disasters and cyber attacks in power network, planning for resilient actions to be employed. The resilience planning methodology for developing and implementing an action plan can include community engagement, policy analysis, vulnerability and risk assessments microgrid modeling, and renewable energy feasibility studies.

International Case Study – Colombia

Power sector resilience is a concern to decision makers around the globe. In 1992, droughts caused by the El Niño effect resulted in widespread power shortages across hydropower-dependent Colombia. The severe shortages precipitated planned blackouts from 8 to 10 h daily across the country. The power rationing was called an “economic crisis” as the estimated cost of the blackouts

Table 2 Environmental impact on using different renewable distributed generations

Name of the methods of distributed generation	CO ₂ gas generation (g/kWh) ^(a)	Water pollution (kg/KWh) ^(a)	Chemical pollutants ^(b)	Land requirement (K m ² /TWh) ^(b)
Fuel cell	50	NA	Very less	NA
Solar	90	10	NA	28–64
Wind	25	1	NA	72
Hydro	41	36	NA	750
Geothermal	170	12–300	NA	18–74
OTEC	NA	NA	NA	NA

^aSource: Kaltschmitt *et al.*^bSource: Lewin, Fritsch *et al.*, also Ackermann; All figures include direct and indirect emissions based on average German energy mix, technology efficiency, solar radiation and typical lifetime.

reached \$35 million per week in lost productivity. The Colombian president at the time, Cesar Gaviria, famously noted that “We will never suffer like this again”. The president even temporarily changed the time zone to take better advantage of daylight hours.

Echoes of the 1992 crisis were heard in 2016 when severe El Niño-caused droughts impacted hydropower availability in Colombia. Through a concerted effort of energy savings and new billing practices, Colombia avoided blackouts despite a 63% reduction in water storage in hydroelectric dams.

Colombia is now preparing for the next El Niño event. The country, which depends on hydropower for over 70% of electricity generation, is seeking to diversify its energy portfolio. Colombia has updated its grid codes to incorporate greater levels of non-hydropower renewable energy-based generation. A new regulation creates a pathway to interconnect distributed generation resources to the grid to provide spatially-diverse, locally-produced power. The first ever, large-scale energy auction in Colombia that incorporates non-hydropower renewable energy was announced in early 2018. The goal of these projects is to provide reliable, cost-effective power to Colombia and to minimize the impacts of El Niño droughts on the Colombia energy sector.

Concerns Regarding Environment

Presently, the policies on environment are the key point for driving force to the demand for renewable distributed electricity generation throughout the world. The regulations on environmental policies play an important role to the electricity market for looking after cost efficient and clean energy generation. Hence, dispersed generation also allows optimization of the energy utilization of industries which have a huge demand for both electricity and heat. Moreover, all the government policies which aim at promoting the practice of renewable will resulting in an increased effect of distributed generation technologies, as renewable, in an integrated nature. The environmental impact of the Renewable distributed generation is presented below in a tabular form (Table 2).

Environmental Impact on Renewable Distributed Generation

The environmental impact of renewable distributed generations like CO₂ generation, Water pollution, Chemical pollutants and also the requirement of land for setting up the Renewable DG plants are discussed below in Table 2.

Conclusions

We initiated the observation on renewable energies as decentralize electricity generation. Prevailing dispersed generation technologies have been discussed so far, its gain and problems of using these technologies are also accounted. More precisely we define the concept of renewable distributed generations. In different environments it appears that many technologies encompasses these new concept by some precise attributes. In a dispersed network, consumer side end directly connected to a power generating source, best explanation of this generation. Resilient, reliable power output is essential for social and economic development. Nonetheless, renewable electricity generation plays a significant role in reducing emissions of greenhouse gas globally and contributing its effect on climate change too. Contemporarily, power systems are very sensible to climate changes. Stubborn challenges are to provide resilient, affordable, reliable power to the consumers. In consonance with this, we identified the challenges and probable solutions in the section considering the need for resilient and reliable output to meet increasing electricity demands for all the countries which are developing and growing, implementing the ideas of renewable generation, enlarge energy

accessibility, while improving distributed generation structure for lowering the emission and improve the environmental aspects and electricity transmission for climate resilience.

Introduction

Presently, use of fossil fuels is the major source of global anthropogenic greenhouse gas emission and this trend is expected to continue over a significant period in future. Coal and natural gas continue as the main primary source of energy for electricity production (IEA, 2015) (Fig. 1).

Hence, replacement of these fossil fuels is not practically feasible in near future though greenhouse gas (GHG) emission from these fossil fuels is the main source of global warming. Use of fossil fuels is mostly responsible for the climate change due to greenhouse gas emission from these fuels (Hansen *et al.*, 2010).

From Fig. 2, it is noted that CO₂ emission from the fossil fuels and industrial processes contributes significantly to the total GHG emission. At the same time, electricity and heat production sector is the largest source of this GHG emission (IPCC, 2014). Reduction of this GHG emission is the global challenge at present for survival of life on earth. Thus, utilization of fossil fuels in a better sustainable way than existing one is a possible way out from this crisis.

Under these circumstances, almost all countries were determined to limit the rise in global average temperature well below 2°C of pre-industrial levels at COP21, Paris in 2015. Several countries adopted different steps to reduce the consumption of fossil fuels and to promote clean technology for power generation as well as other industrial processes. Different Governments are imposing additional tax on carbon based fuel production or use to discourage its use. For example, Government of India imposed carbon tax on coal at a rate of INR 400 per tonne to raise funds for research on clean energy and to promote the clean environment. At the same time, many countries are in transition phase towards low carbon economy. They are promoting for low carbon life style and communities for sustainable development. Thus, coal and natural gas are not considered as clean fuels from the viewpoint of sustainable energy. Several technologies are explored to utilize coal in a more sustainable way. Carbon capture and storage (CCS) is considered to be the option of using fossil fuels with low GHG emission. CCS has good potential to mitigate carbon footprint of fossil fuel use as well as it has the potential of net carbon negative electricity generation through biomass based energy system integrated with CCS. However, significant cost increase is inevitable due to CCS. For CCS technology, CO₂ is captured before or after the combustion of fossil fuels and from other industrial processes e.g., iron and steel production, cement production etc. In this article, different CO₂ capture technologies e.g., post-combustion, pre-combustion, oxy-fuel combustion and chemical looping are discussed. Different aspects of CO₂ compression, transportation and storage are included. Application and integration of CCS in power industry, iron and steel industry, chemical process are shown in this article. Advanced carbon capture technology like carbon capture and utilization (CCU), BECCS are also explored. Finally, challenges and opportunities of CCS are also mentioned.

Properties of Carbon Dioxide

Properties of CO₂ are necessary to model the processes of carbon dioxide capture, compression, liquefaction, transport and storage. In Table 1, different thermodynamic and transport properties of CO₂ are given (IPCC, 2005). To simulate the carbon capture by amine, thermodynamic properties as well as viscosity are required. As CO₂ is compressed and liquefied before transportation through different mode, thermodynamic properties of CO₂ determine the optimum pressure of liquefaction. Also density of CO₂ has significant impact on storage volume. There are significant effects of impurities (say, SO₂) on the property of CO₂.

Overview of Carbon Capture Technology

Electricity sector is the main source of anthropogenic greenhouse gases. Apart from power generation other sources of GHG emission are iron and steel production, cement production and petro-chemical processing where CCS technology may be implemented as shown in Fig. 3. Iron and steel industry contributes 31% of industrial emissions (IEA, 2013). For each ton of cement production around 880 kg of CO₂ is emitted. Petrochemical processing is another important sector responsible for GHG emission. From these sectors CO₂ can be captured and stored as shown in Fig. 3. Detail of CO₂ emission and potential of CCS is discussed later.

In Fig. 4, basic principle of a power plant with different methods of carbon capture against that without any carbon capture is shown. In a basic power plant, fuel and oxidizer (say, air) are the inputs and power is the output. Flue gas containing CO₂ is a hazardous effluent of the power plant. Efficient separation and storage of this CO₂ in different ways is the main research challenge. Basic overview of post-combustion CO₂ capture is shown in Fig. 4(b). In this process CO₂ is captured after the complete combustion of fuels. In pre-combustion process, CO₂ is captured subsequent to gasification process i.e., before the complete combustion of syngas as shown in Fig. 4(c). In oxy-fuel combustion process, combustion of fuel takes place in

Table 1 Properties of carbon dioxide (CO₂)

Property name	Value
Molecular weight	44.01
Critical temperature	31.1°C
Critical pressure	73.9 bar
Triple point temperature	− 56.5°C
Triple point pressure	5.18 bar
Boiling point (sublimation) at 1.013 bar	− 78.5°C
<i>Gaseous phase</i>	
Gas density at standard temperature and pressure (STP)	1.976 kg/m ³
Specific volume at STP	0.506 m ³ /kg
C _p at STP	0.0364 kg/mol-K
C _v at STP	0.0278 kg/mol-K
Specific heat ratio (C _p /C _v) at STP	1.308
Viscosity at STP	13.72 μPa s
Thermal conductivity at STP	14.65 mW (m/K)
Solubility in water at STP	1.716 vol/vol
Enthalpy at STP	21.34 kJ/mol
Entropy at STP	117.2 J mol/K
Enthalpy of formation at STP	213.8 J mol/K

presence of pure (90%–95%) oxygen. Hence, flue gas contains mainly CO₂ and H₂O. CO₂ can be separated by condensing moisture in the flue gas and simple purification process as shown in Fig. 4(d). More details of these processes are discussed later.

Overview of Materials for Carbon Capture

The most matured technology for low partial pressure CO₂ capture is done by amine solvents. It is the most matured technology till date. It is benchmarked against pilot scale setup. Three types of amines are used in CO₂ capture process as shown in Fig. 5.

However, most commonly used amine is monoethanol amine (MEA). In present benchmarked technology 30% aqueous MEA solvent is used to capture CO₂ from the flue gas. In this process 90% CO₂ of the flue gas may be captured. Though energy penalty

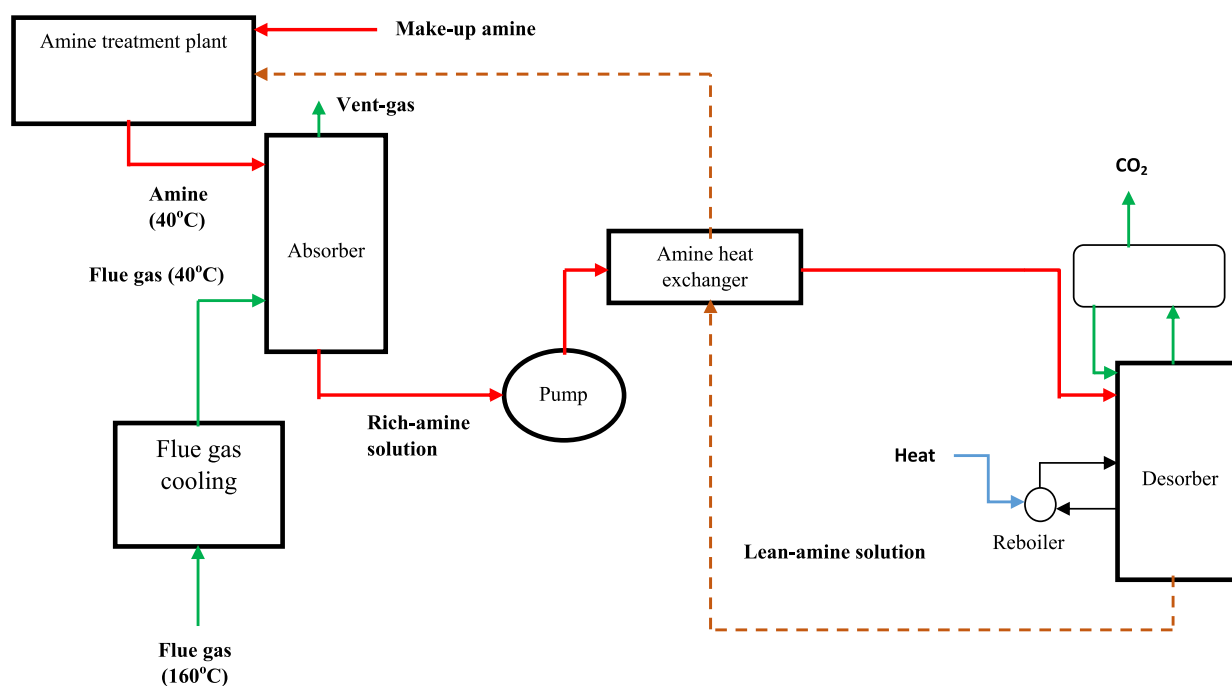

Fig. 6 Basic schematic of amine based CO₂ capture process. Reproduced from Jana, K., De S., 2016. Utilizing waste heat of the flue gas for post combustion CO₂ capture – A comparative study for different process layouts. *Energy Sources, Part A: Recovery, Utilization, and Environmental Effects* 38, 960–966.

is observed in form of reboiler heat duty at a rate of 3.6–4 GJ per tonne of CO₂ captured. Detailed reaction of aqueous MEA solution with CO₂ is given below.

Fig. 7 Type of adsorbents for CO₂ capture.

Fig. 8 Schematic of CO₂ compression, transportation and storage. Reproduced from Rackley, S.A., 2017. Carbon Capture and Storage, second ed. UK: Butterworth-Heinemann.

One of the primary objectives for development of amine properties is to reduce reboiler heat duty. Thermal degradation and oxidative degradation as well as moderate toxicity are the major disadvantages of MEA based CO₂ capture. For these reasons, development of novel sorbents is being explored. Aqueous piparazine (PZ) and 2-amino-2-methyl-1-propanol (AMP) has been studied for CO₂ capture. In some cases, blending of amines is used for experiment where one amine may complement other(s) and blending will be decided accordingly. As MEA is the most matured technology, schematic of MEA based CO₂ capture is shown in Fig. 6.

In this process, initially flue gas is cooled to 40°C. SO₂ may be removed from flue gas before entering into the absorber column. In absorber column, CO₂ is absorbed by aqueous amine solution at 40°C. Then the solution becomes rich with amine. Pressure loss in the absorber column and stripper column is compensated by pressurizing the solution using pump. Before entering to stripper column, the rich amine solution is preheated by returning lean amine solution. In stripper column, rich amine solution is heated in reboiler section. In this column, CO₂ is separated from amine solution and CO₂ is obtained in the condenser section of the stripper column.

Apart from absorption process, adsorption is a promising option for CO₂ capture from flue gas (Choi *et al.*, 2009). In this process CO₂ is held on the surface of adsorbing material and it is regenerated by applying various techniques like pressure swing adsorption (PSA) or temperature swing adsorption (TSA). Better selectivity, higher capacity and better tolerance to the impurities are the main research area of adsorption based CO₂ capture. Also reducing the energy intensity of the process is another area of

Fig. 9 Schematic of power generation with post-combustion CCS.

Fig. 10 Schematic of power generation with pre-combustion CCS.

research. Different types of adsorbent are shown in Fig. 7. In general, adsorbent materials are organic, inorganic, inorganic hybrid and metal organic framework. However, this adsorption process for CO₂ capture is yet to be commercially available. It is at the research and development stage.

CO₂ Transportation and Storage

After capturing CO₂, it has to be transported to the suitable sites for storage. Transportation may be done by pipeline, by container or by ships. Transportation technology is matured for gas transportation, oil transportation or water transportation. Transportation of CO₂ at atmospheric pressure is difficult due to its large volume. The schematic of various steps of CO₂ compression, transportation and storage is shown in Fig. 8. Before CO₂ is compressed, it is conditioned to remove impurities like H₂S and other corrosion elements. Then it is compressed and transported to the desired site. The compression may be done in multiple steps of intercooling to reduce the energy consumption. However, pressure of CO₂ transportation is maintained between 10 and 80 MPa. Otherwise it is liquefied and transported through container and then by ships. Pipeline should be avoided from populated area to avoid the risk of leakage.

After transportation, CO₂ is stored in various ways like geological storage, ocean storage and mineral carbonation. It may be used for value added services like enhanced oil recovery (EOR), enhanced coal bed methane (ECBM) recovery etc. These are the geological storage options for CO₂ capture. However, EOR and ECBM are commercially available. In geological storage, CO₂ is stored under suitable impermeable rock formations (caprock). However, cost of CO₂ storage depends on site and it may vary widely from 0.6 to 8.3 US\$ per tonne of CO₂ (IPCC, 2005). CO₂ may be stored in depleted oil and gas reservoir where oil and gas was stored due to suitable geological formation. However, leakage should be avoided. It may create health hazards for local plant or may affect local minerals. Ocean can be a great storage option for CO₂. In this process CO₂ is injected into the ocean from ship or suitable pipeline at a certain depth. In ocean, CO₂ may be kept away from the atmosphere for centuries. CO₂ may be stored in the form of inorganic carbonates or may be utilized for value added products as discussed later.

Integration of CCS

In Fig. 9, schematic of carbon path in post-combustion CO₂ capture is shown. From the figure it is noted that combustion of carbon containing solid or liquid fuel (mainly coal) takes place in combustion chamber or in furnace with an oxidizer like air.

Fig. 11 Schematic of power generation with oxy-fuel combustion.

Fig. 12 Chemical looping combustion for CO₂ separation.

Then hot flue gas passes through the steam generator or boiler. It transfers heat to generate steam which is used in steam turbine for power generation. Then flue gas is cleaned for solid particles with filters or electrostatic precipitator (ESP) for coal based power plant. After that flue gas is cooled down to 40°C for applying MEA based CO₂ capture process as discussed earlier. After capturing the CO₂, it is compressed, then transported and stored in suitable site. However, this carbon capture process may be integrated with newly designed plant or it may be retrofitted with existing plant. Hence, for existing plant post combustion CO₂ capture process is preferred.

In **Fig. 10**, power generation with pre combustion carbon capture process is shown. In this process carbon containing fuel is not directly combusted. It is gasified or pyrolyzed to produce a syngas. Depending on the fuel properties and operating condition of the gasifier, syngas may contain H₂, CO₂, CO, H₂O, CH₄ with varying fractions. To decrease the CO percentage and to increase the CO₂ content in the syngas, water gas shift (WGS) reaction is executed in the WGS reactor as shown in **Fig. 10**. In this process, steam is the input to convert CO and to produce H₂ in the presence of suitable catalyst. To avoid catalyst poisoning, depending on the type of catalyst gas cleaning process is done before the WGS reaction. After WGS reaction, CO₂ content in syngas becomes high and it may be captured by various commercial solvents like Selexol[®], Rectisol[®] etc., CO₂ is further transported and stored at suitable location. After capturing CO₂, syngas becomes H₂-rich. This H₂ may be directly used in fuel cells or may be used for combustion in gas turbines (GT), combined cycle gas turbines (CCGT) or in steam generators of steam turbine (ST) cycles.

Another option for CO₂ capture is oxy-fuel combustion. The schematic of power generation through oxy-fuel combustion is shown in **Fig. 11**. In this process, combustion takes place with almost pure oxygen. To produce pure oxygen (90%–95%), air separation unit (ASU) is integrated. It requires significant amount of energy. It is the main drawback of this process. After

Fig. 13 Sources and options for CO₂ emission reduction in steel production process.

Fig. 14 Sources and options for CO₂ emission reduction in cement production process.

combustion flue gas contains mainly H₂O and CO₂. CO₂ is separated after the condensation and further distillation of the flue gas. Then separated CO₂ is compressed, transported and stored at the desired location.

Chemical looping combustion process is shown in Fig. 12. In this process oxygen is carried by metal oxides. In air reactor, metal oxide reacts with air and becomes oxidized. Then it is transported to the fuel reactor. However, in this reactor, fuel is oxidized and metal oxide is reduced. Then the reduced metal oxide is fed to the air reactor for oxidation. Similar to oxy-fuel combustion, in this process, flue gas contains only H₂O and CO₂. By condensing the flue gas, CO₂ may be separated in a comparatively easier process.

In steel production, significant amount of CO₂ is emitted. In 2010, total CO₂ emission was 2500 million tonnes from steel industry. In this process several sources of direct and indirect CO₂ emission are observed. In Fig. 13, sources as well as potential for reduction of CO₂ is shown. The main source of CO₂ emission is coking coal which is used to reduce iron ore. To produce 1 tonne of steel 770 kg of coking coal is required (ULCOS, 2013). Apart from coking coal, electricity and limestone inputs are the other sources of CO₂ emission in steel production. To reduce the carbon intensity of steel production, post combustion CO₂ capture may be integrated with steel production process. Increase in energy efficiency and/or waste heat recovery is other option. Apart from these, use of renewable energy, efficient process design and utilization of products may reduce carbon emission from steel production. Another significant carbon intensive process is cement production. The sources and potential options to reduce CO₂ emission is shown in Fig. 14 (IEAGHG, 2013). In cement production process clinker is the main source of CO₂. Indirect emission due to electricity use and direct emission due to fuel combustion are the other two sources of CO₂ emission. To reduce CO₂ emission, integration of CCS and improvement in energy efficiency may be implemented. Use of alternative fuels and materials and low clinker to cement ratio may improve carbon intensity of the cement production process.

Options for Carbon Capture and Utilization

As stated earlier, carbon capture is energy intensive process and it is reflected on the economic performance of the plant. It reduces the output electricity. As a result, per unit electricity prices increases. Also significant economic investment is required. This may be offset by utilizing the captured CO₂ to value added product and services (Hu et al., 2013). In Fig. 15, different source of CO₂ and its utilization pathways are shown. The captured CO₂ may be used directly in enhanced oil recovery, enhanced gas recovery. In

Fig. 15 CO₂ capture and utilization (CCU) pathways.

Fig. 16 Biomass based power generation integrated with carbon capture and storage.

these cases, CO₂ is transported and injected into the geological rocks where recovery of oil and gas are enhanced. CO₂ may be used in polymer processing, food processing. It may be used as refrigerant media also. Algae cultivation is one of the promising areas of CO₂ utilization. For this case the growth of algae is enhanced by consuming captured CO₂. There are mainly three routes for conversion of CO₂ into value added products. These are thermal, electro-chemical and photo-chemical. The conversion of CO₂

Cost of CO ₂ captured (US\$/t CO ₂)	23–35	11–32	33–57
Cost of CO ₂ avoided (US\$/t CO ₂)	29–51	13–37	37–74

Note: IPCC, 2005. IPCC Special Report on Carbon dioxide Capture and Storage. New York: Cambridge University Press.

mainly depends on the catalyst development. Good energy efficiency, high conversion rates are other parameters to consider successful applications of CO₂ utilization. To convert CO₂, input energy is preferred from renewable resources like solar energy, wind, biomass to reduce the overall life cycle CO₂ emission. In this conversion, CO₂ may produce fuels like CO, CH₃OH, HCOOH etc., or it may produce chemicals like urea, polymers etc., as shown in Fig. 15.

Negative-CO₂ Emission Technology

To reach the 'goal of 2°C', net-CO₂ negative plant can be a suitable option. When CO₂-neutral fuel is used with CO₂ capture, then net life cycle CO₂ emission may become negative. Biomass is a suitable net-CO₂ neutral fuel. In this case, CO₂ absorbed during its growth phase is equivalent to the CO₂ emission during its use. However, transport and other logistics of biomass may add some CO₂ to the environment. Otherwise, direct air capture (DAC) of CO₂ may be a net negative-CO₂ emission technology. In Fig. 16, schematic of a biomass based power generation with carbon capture and storage is shown. In this process, firstly, woody biomass or agricultural residues are collected. Then it is pre-processed and transported. After that combustion or gasification process is done to produce hot flue gas or syngas. Flue gas or syngas is utilized for gas turbine or steam turbine power generation. CO₂ is captured from the flue gas (post combustion capture) or H₂-rich syngas (pre combustion capture). Then the captured CO₂ is compressed, transported and stored. Direct air capture (DAC) is another net negative CO₂ technology. In this process CO₂ is captured from the air and stored.

Status of Present Carbon Capture and Storage Technology

In the context of COP21 and Paris agreement, carbon capture and storage technology will have significant impact to keep the temperature rise below 2°C of pre-industrial age. Though a few projects are commercially operating, many areas need suitable research and development for successful implementation of CCS. The different stages associated with CO₂ capture, transport, storage and utilization technology are given in Table 2. From the table, it is noted that CO₂ capture by aqueous amine

solution was commercially available for natural gas processing. Also on-shore and off-shore pipeline is commercially available for EOR projects. Transportation by ship and saline formation technologies are also commercialized. However, pre-combustion CCS for IGCC, adsorption CO₂ capture, direct air capture etc., are in demonstration stage only. Chemical looping, non-EOR CO₂ utilization etc., are in pilot plant stage. Further research is needed to commercialize these technologies. Other technologies of CCS and utilization are at lab scale. Suitable research and development is necessary to scale-up and successful implementation of these technologies through commercialization. However, performance of newly built plant with or without CCS is given in Table 3. In this table, potential of CCS to reduce CO₂ emission and its economic penalty are given. It is noted that significant amount of CO₂ emission can be avoided through CO₂ capture. However, it decreases the overall plant efficiency and hence cost of electricity increases. As a result, significant economic penalty is generally inevitable to avoid CO₂ emission.

Conclusion

Anthropogenic CO₂ emission is the main reason behind global warming. CCS may play an important role in this context to reduce the anthropogenic CO₂ emission from the energy sector. Though CCS is facing many challenges, a few technologies of CCS are commercialized, say, amine based post combustion CO₂ capture was in operation previously in the case of natural gas processing. However, many advanced CCS technology are in the stage of research and development or in laboratory scale. Absorption, adsorption, oxy-fuel combustion and chemical looping are mostly the available technologies of CO₂ capture. However, monoethanol amine (MEA) based post combustion CO₂ capture is the most matured technology. Off-shore and on-shore pipeline transportation and transportation by ships are commercially available technologies. Utilization of CO₂ for enhanced oil recovery is presently being used in practical operation. However, other CO₂ utilization technologies such as chemical production, fuel production need further research and development. Bioenergy with CCS and direct CO₂ capture from air are the options for net negative CO₂ emission. Apart from energy sector, CCS may be integrated with carbon intensive industries like iron, steel, cement industries also.

Introduction

Industrial revolution and economic growth are accumulatively accelerating the urbanization and change in societal way of living. This factor along with population explosion is directing the whole community towards the consumption of non-renewable resources. The shifting trend from renewable to non-renewable resources is leading to the generation of waste mountains and addition of a large volume of long-lived Greenhouse Gases (GHGs) e.g., (CO_2 , CH_4 , N_2O) and several other fluorinated gases into the atmosphere ([Environmental Protection Agency \(EPA\), 2016a](#)). Solid wastes make an entry into the main stream in the form of MSW and creates various environmental and health hazardous issues ([Environmental Protection Agency \(EPA\), 2009](#)). In 2011, worldwide the amount of MSW is around 2 billion tones and the growing rate is faster than urbanization. It is expected that this faster growing rate will accelerate the waste generation which will touch 10 billion tons within 2050 ([Chen, 2016](#)). Thus, proper handling and disposal of MSW through an environmental friendly, economically viable system is an utmost necessity for every nation in this world ([Intergovernmental Panel on Climate Change \(IPCC\), 2006a](#); [Rajaeifar et al., 2017](#)). Now days, waste disposal system is categorised in regular (like landfilling, incineration) and proximal (like Refuse derived fuel, gasification) methods. In general, regular processes are found to work more in number than the proximal ones, however, the harmful impact on environment is also more prominent in case of regular ones. Incineration and landfilling are the more common practices among the waste disposal systems. Presently, landfilling is executed to minimize the waste amount from our living space by simply dumping in a particular area. Subsequently, Incineration is become another frequent practice to minimize the waste volume by simple burning in a concise place or chamber. These practices are effectively causing high amount of greenhouse gas emission and health hazard issues for livelihood as well as for the environment. Despite of requirement of large land and transportation cost, most frequently landfilling is used for waste disposal but it is also responsible for adding high extent of GHGs to the atmosphere. Similarly, incineration can be beneficial in line with waste volume destruction but in addition it releases environmentally toxic greenhouse gases like SO_x , NO_x ([Wanga et al., 2017](#)) too and other hazardous chlorinated dioxins and furans ([Rajaeifar et al., 2017](#)).

In greenhouse gas emission related issues, it was estimated that globally around 46 billion metric tons of greenhouse gases were emitted in our environment during 2010 by only human activities ([Environmental Protection Agency \(EPA\), 2016b](#)). The energy generation sectors are one of the major contributors of GHGs to the atmosphere. In 2010, annual CO_2 emissions from these sectors were about 25% of total CO_2 emissions throughout the world. Some other sectors like agriculture, forestry, other land use together contribute 24% while industry alone contributes about 21% ([Intergovernmental Panel on Climate Change \(IPCC\), 2014](#)). Waste and waste disposal methods contribute a 3%–4% share of total GHGs emission ([Intergovernmental Panel on Climate Change \(IPCC\), 2006b](#)). However on the basis of per capita GHGs emission India stands on the fourth position in GHGs release throughout the world. After China, USA and European Union, at present India is holding this position releasing around 3000 metric tons of GHGs which is only 6.5% of total GHG emission. Similarly, continuous economic growth and population expulsion directed towards rapid urbanization which makes Indonesia, Brazil, Mexico and Iran a bigger contributor to the total world GHGs emission ([Baumert, 2017](#)). But it has been observed that during 1994 and 2007 the rate of GHG generation from waste products disposal has increased to about 7.3% while total 6% increase has been observed in the others sectors like electricity, transport, energy, residential, agriculture, cement, iron and steel plant ([INCCA: Indian Network for Climate Change Assessment, 2010](#)).

Reduction of waste generation at source is very much less effective that makes the waste generation and resource consumption a parallel process. Improper waste management and GHGs emission are the inevitable process. Thus proper waste management can minimize the waste quantity and as well as can reduce the GHGs emission for the waste sectors. In this regard, the proximal process plays an efficient role with high volume reduction efficiency and minimal release of toxins ([Rajaeifar et al., 2017](#)).

Accounting for suitable methods, Plasma arc technology is marked as most efficient methods with high waste destruction efficacy, negligible amount of toxin release, producer of high calorific value syngas which assists in energy recovery. The residual part is vitrified into a non-leachable inert material like slag which is very good constituent in developing building as constructional materials ([Janajreh et al., 2013](#)). In the wastes generated the main counterparts of MSW are solid combustible materials like plastic, textile, paper which has high energy recovery potential ([Rajaeifar et al., 2017](#)). In this technology, organic materials directly come in to contact with the high temperature plasma flame operated by plasma torches. In this plasma driven operation CO_2 emission is

reasonably less owing to the absence of O₂ like oxidant (Byun *et al.*, 2010). It also restricts the formation of various toxic pollutants like dioxin, furan (Gomez *et al.*, 2009; Moustakas, 2005). Oxygen starved condition also helps to break down the waste material into gases which have high content of syngas (CO, H₂). It can be utilised in a gas engine for electricity generation or used as a feed stock for generation of bio-fuels like methanol, which is a next generation fuel. Methanol is always a suitable option for fuel cells as a source of hydrogen. In production of some important synthetic fuels like dimethyl ether (DME), methanol is used as an intermediate chemical (Ma *et al.*, 2009). In future, methanol can help to meet the energy requirement either through direct use or as indirect feed stock. It clearly indicates the necessity of methanol production in cost effective way which is of utmost necessity. Syngas is a prime feedstock for methanol production due to high content of carbon monoxide (CO) and hydrogen (H₂). Conventionally, natural gas and oil are the main source of syngas but uninterrupted supply of these sources is not affordable in coming days. Exhaustive use and uncontrollable burning of fossil fuel has already stood our environment in facing a serious threat about Global warming due to massive GHGs emission (Bermúdez *et al.*, 2010). Syngas production from MSW through gasification by a plasma arc driven system is an energy efficient method. Herein the feedstock comprises of discarded waste materials, indicates its cost effectiveness in production of syngas as well as in production of methanol. This approach could be a solution to reduce the use of fossil fuel and finally a significant reduction in GHGs emission.

Implementation of plasma arc technology in MSW destruction with energy recovery could be an effective solution towards GHGs emission. The significance of this method is that the outcome products can be further utilised for electricity, heat or fuel generation. This concept has unique points like reducing the dependency on renewable resources, decreasing the fossil fuel consumption which leads to lessening the emission of Greenhouse Gases (GHGs). Accordingly, waste consumption in energy recovery process leads to high volume reduction and reduces the load on landfilling. Waste to energy generation is now-a-days a rising process path throughout the world for producing energy (Rajaeifar *et al.*, 2017).

Results and Discussions

Municipal Solid Waste

Municipal solid waste is the most frequently generated waste around the world. Its composition depends on geographical position, population, people's life style, economic growth, urbanization, *etc.* For this reason there is a significant variation in MSW composition and total waste generation. In respect of waste generation, United States of America (USA) comes first in the list with 254.1 million tons of MSW generated in 2013. A sudden surge in waste generation has been observed from 1960 to 2013 *vide* (Table 1; Rajaeifar *et al.*, 2017).

In this timeline, there is a significant increase in population which results in increment of quantity of MSW generation as well as the per capita MSW generation. During the same period, there is two-third time increment in Per capita MSW generation (Environmental Protection Agency (EPA), 2013, 2015; United States Census Bureau, 2015). Accordingly, European Union (EU) with its 27 member in 2013 generates around 241 million tons of MSW. From 1995, population and waste generation increases abnormally in a linear fashion, while there is slight increase in average per capita waste generation (0.2 kg/person/day) (Table 2; Rajaeifar *et al.*, 2017). However, the variation rang of per capita waste generation is very much wide (747–272 kg) depending upon the population distribution, global position and waste management processes *etc* (European Commission statistics (Eurostat), 2015a, 2015b; European Environment Agency (EEA), 2015).

In respect of per capita MSW generation, Australia is one of the major contributors. But surprisingly; there is a fall (7.6%) in per capita MSW generation during 1980–2013 (Table 3). This value of per capita generation reside at 1.77 (kg/person/ day) in 2013 which is also significantly high (Statista, 2015; Australian Bureau of Statistics, 2015; Organisation for Economic Co-operation and Development (OECD), 2015a, 2015b).

Table 1 Total MSWs generation (in million tons) in the USA with increasing Population (in million) during 1960–2013

Year	Population (million)	Total MSW generation (million tons)	Per capita generation(kg/person/day)
1960	180.7	88.1	1.22
1965	194.3	104.4	1.34
1970	205.1	121.1	1.47
1975	216	127.8	1.47
1980	226.5	151.6	1.66
1985	237.9	166.3	1.74
1990	249.6	208.3	2.07
1995	266.3	217.3	2.05
2000	282.2	243.5	2.15
2005	295.3	253.7	2.13
2010	309.3	250.6	2.01
2013	316.5	254.1	2.00

Table 2 Total MSWs generation (in million tons) in the European Union (EU)-27 with increasing Population (in million) during 1960–2013

Year	Population (million)	Total MSW generation (million tons)	Per capita generation(kg/person/day)
1995	476.96	225.60	1.30
1999	481.63	246.11	1.40
2003	486.33	249.98	1.41
2005	491.39	253.56	1.41
2006	493.00	257.35	1.43
2007	494.78	259.26	1.44
2008	496.75	258.81	1.43
2009	498.96	254.97	1.40
2010	499.93	251.96	1.38
2011	500.51	249.25	1.36
2012	499.95	244.48	1.34
2013	502.16	241.54	1.32

Data Source: Rajaeifar, M.A., Ghanavati H., Dashti, B.B., *et al.*, 2017. Electricity generation and GHG emission reduction potentials through different municipal solid waste management technologies: A comparative review. *Renewable & Sustainable Energy Reviews* 79, 414–439.

Table 3 Total MSWs generation (in million tons) in the Australia with increasing Population (in million) during 1960–2013

Year	Population (million)	Total MSW generation (million tons)	Per capita generation(kg/person/day)
1980	14.69	10.28	1.92
1999	17.07	11.78	1.89
2000	19.15	13.22	1.89
2009	21.78	14.09	1.77
2010	22.07	14.30	1.78
2013	23.10	14.95	1.77

Data Source: Rajaeifar, M.A., Ghanavati H., Dashti, B.B., *et al.*, 2017. Electricity generation and GHG emission reduction potentials through different municipal solid waste management technologies: A comparative review. *Renewable & Sustainable Energy Reviews* 79, 414–439.

Continent wise, most wide range of variation in per capita waste generation is observed in Asia due to largest land area and diversity in population density. There is large difference in amount of annual waste generation and average per capita generation among the different regions of Asia. Almost 270 million tons of MSW generated from the East Asia and the Pacific Region with an average of 0.95 per capita (kg /person/day) generation. Though this per capita value is varies from 0.44 to 4.3 kg over 15 major countries of this region (**Fig. 4**) (Rajaeifar *et al.*, 2017). Among these countries, China contributes around 70% of total waste generation by this region. Eastern Europe & Central Asia region and South Asia region are on the verge of becoming the next two major contributing domain of Asia with an annual generation of 93 million tons and 70 million tons of MSW respectively. Whereas, Middle East & North Africa region generates around 63 million tons of MSW per year but the average per capita generation (1.1 kg/ person/day) is similar to Eastern Europe & Central Asia region and higher than South Asia region (0.45 kg/ person/day). The average per capita MSW generation of these regions are mainly dependant on the average per capita MSW generation by the countries depicted in the respective regions (**Fig. 1**; Rajaeifar *et al.*, 2017).

In 2012, Sri Lanka holds the highest average per capita MSW generation (5.1 kg/Capita/day) in south Asian region of Asia (**Table 4**; Hoorweg and Bhada-Tata, 2012). Comparatively in case of total MSW generation, very unfortunately India holds the leading role with 109,589 ton per day. This clearly indicates there is a sharp increase in the total annual MSW generation in every region as well as countries around this globe (Hoorweg *et al.*, 2005; Hoorweg and Bhada-Tata, 2012).

In Indian context, the situations are becoming worse considering its uncontrolled growth in population, and economical growth. brief survey reflect, India in his mid ninety's has very lesser extent of MSW (6 Million tons), however uncontrolled waste generation and unscientific waste management, mass level unawareness leads India to a huge crisis of piling near about 50 million tonnes of MSW in its 50th independence anniversary. Shockingly, in it's coming diamond jubilee it might approximately attain 300 million tons (Sharholly *et al.*, 2006). A brief sketch of total waste generation in a limited time frame is depicted for India's forty six major metro cities (**Table 5**) (CPCB: Solid waste generation in metrocities, 2017). The analysis that clearly reveals that the mega cities like Mumbai, Delhi, Kolkata, Chennai *etc.* are gathering MSWs at an alarmingly rate in the last ten years. Proper initiatives and timely action in stopping uncontrolled waste generation is the urge of the present century.

Waste Composition

Worldwide composition of MSW can be categorised in nine different types which are generated from various sources with the relative proportion *vide* (**Table 6**; Hoorweg and Bhada-Tata, 2012).

Fig. 1 Per capita MSWs generation in different regions in Asia. Data Source: Rajaeifar, M.A., Ghanavati H., Dashti, B.B., *et al.*, 2017. Electricity generation and GHG emission reduction potentials through different municipal solid waste management technologies: A comparative review. *Renewable & Sustainable Energy Reviews* 79, 414–439.

Table 4 Variation of waste generation in different countries of South Asian region

Sl no.	Countries	Total MSW generation (tonnes/day)	MSW generation per capita (kg/ capita/day)
1.	India	109,589	0.34
2.	Pakistan	50,438	0.84
3.	Nepal	427	0.12
4.	Maldives	175	2.48
5.	Sri Lanka	15,068	5.10
6.	Bangladesh	16,384	0.43
7.	Bhutan	329	329

Data Source: Hoornweg, D., Bhada-Tata, P., 2012. What a waste: A Global Review of Solid Waste Management. Washington, D.C: Urban Development & Local Government Unit, World Bank.

The variations of proportion in waste composition are also highly influenced by populations, economic development, geographical location, climate and cultural versatility *etc.* An urbanised country with economically rich people generates more inorganic fraction than organic ones in MSW. Similarly, percentage of these 6 types also effectively varies with income and shows that countries that possess higher income level are having lower organic fraction in comparison to the other income levels (Fig. 2; Rajaeifar *et al.*, 2017). Construction and demolition waste (C&D) like debris, concrete are also noticeable composition in waste materials. Here, construction and demolition waste is not taken in consideration due to its ineffectively in energy recovery process.

Table 5 Variation of waste generation in Indian cities during 1999–2016

Rank	City	Waste Generation (TPD)			
		1999–2000	2004–2005	2010–2011	2015–2016
1	Mumbai	5355	5320	6500	11,000
2	Delhi	400	5922	6800	8700

Data Source: CPCB: Solid waste generation in metrocities, 2017 Solid waste generation in 46 metrocities: Central Pollution Control Board, India. Available at: http://cpcb.nic.in/uploads/hwmd/trend_46_cities_list.pdf.

This type of variation in MSW composition is usually deviated from region to region across the globe. In country wise material is a common phenomenon. For example in India, MSW mainly comprises of organic fractions along with waste paper, synthetic materials, waste glass, metal, inert material. This variation of MSW composition is mainly influenced by population variation in cities *vide* (Table 7; Gupta *et al.*, 2015).

On the other hand, MSW can also be classified into compostable matters and recyclable materials. Bio-Organic wastes like fruit and vegetable peels, food wastes are mainly considered as compostable matters. In this context, recyclables materials are enriched with plastic, paper, glass and metals *etc.* and moreover toxic substances like used batteries, paints, medicines, pesticides, *etc.* are common contaminants. Physical characteristics also varying from place to place and in Indian megacities (Delhi, Mumbai, Kolkata, Bangalore, Chennai) and these variations are clearly visible. Other cities and capital are having

Table 6 Different type of MSW and composition generated from different sources

Sl No.	Types	Sources	Composition
1.	Organic	Food scraps, yard (leaves, grass, brush) waste, wood, process residues	46%
2.	Paper	Paper scraps, cardboard, newspapers, magazines, bags, boxes, wrapping paper, telephone books, shredded paper, paper beverage cups. Strictly speaking paper is organic but unless it is contaminated by food residue, paper is not classified as organic	17%
3.	Plastic	Bottles, packaging, containers, bags, lids, cups	10%
4.	Glass	Bottles, broken glassware, light bulbs, colored glass	5%
5.	Metal	Cans, foil, tins, non-hazardous aerosol cans, appliances (white goods), railings, bicycles	4%
6.	Other	Textiles, leather, rubber, multi-laminates, e-waste, appliances, ash, other inert materials	18%

different proportion of compostable and recyclables materials (**Fig. 3; Waste Generation and Composition: Central Pollution Control Board, India, 2017**). Depending on the sources, generated MSW may be comprised of soiled waste like waste cotton, blood stained clothes, disposable syringes, sanitary napkins *etc.* which are highly infectious in line with spreading various types of diseases (Jha *et al.*, 2003).

Conventional Methods of MSW Disposal

Safe disposal of MSW is the most crucial and challenging part of waste management maintaining the environment balance and a healthy human life. Accordingly, an efficient technology for safe disposal of MSW is required to meet the environmental cleanliness. There are so many remedial methods to dispose generated MSW but no one of the existing methods is suitable enough to consider all aspects of MSW disposal. Here first of all, composting and vermi-composting are most general techniques to deal with the compostable parts of MSW. The generated manure with some amount of bio-methane (bio-gas) is one of the value added end products of this technology. Nature of wastes materials is an important factor for commercial applicability of these methods. Besides, landfilling is the most common waste disposal method for worldwide disposal of generated MSW which is also due to low cost of such technology. Landfilling is an open field where wastes are only dumped

Fig. 3 Variation of compostable and recyclable material in MSW in Indian cities. Data Source: Waste Generation and Composition: Central Pollution Control Board, India, 2017. Available at: <http://cpcb.nic.in/waste-generation-composition/>.

periodically and consequently it becomes a breeding place for insects, vermin or a snitching place for rag pickers. Contaminants and toxins are exposed to the environment by these type of carriers (insects, vermin, rag pickers) (Gupta *et al.*, 1998; Giusti, 2009). In addition, Landfilling is a well known source of greenhouse gases (GHGs) among the other man made sources of greenhouse gases (GHGs). Carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) like gases is the major contributor of GHGs (Intergovernmental Panel on Climate Change (IPCC), 2013). It is estimated that in 2004, CH_4 emissions from landfills is approximately 18% of global anthropogenic CH_4 emissions. Analysis of different collective data indicates that there is a wide variation in landfill CH_4 emission during 1990–2015 (Fig. 4; Bogner *et al.*, 2008). Furthermore, it is estimated that the amount of CH_4 emission will be increased by more than three times by the middle of this century from the cities where landfilling is the major way of waste mitigation (Bogner *et al.*, 2008).

Based on reported emissions from national inventories and national communications, and (for non-reporting countries) on 1996 inventory guidelines and extrapolations (US EPA, 2006).

Based on 2006 inventory guidelines and BAU projection (Monni *et al.*, 2006).

However the requirement of large dumping space restricts the application of landfilling in many places. Here also the non-biodegradable parts of MSW are creating more problem than the compostable ones. some of non-biodegradable parts are further

Fig. 5 Number of incineration in operation during 1968–1990 in European countries. Data Source: McKay, G., 1996. Dioxin characterisation, formation and minimisation during municipal solid waste (MSW) incineration: Review. Chemical Engineering Journal 86, 343–368.

recycled and rest are dumped in an unscientific manner. Their long lifetime and large volume of generation makes these wastes a threat to the environment. Consequently, incineration is one of the most frequently use method for drastic volume reduction of MSW. There is a significant increase in the number of incineration plants used and there operating capacities during 1965–1990 in Europe (Fig. 5; McKay, 1996). Incineration is a thermal treatment process where waste materials are combusted in presence of oxygen in a confined system. Herein, presence of air helps in releasing toxic gases comprising of high extent of GHGs. Apart from high percentage of CO, CO₂, HCl, SO₂, some other toxic elements like dioxins, furans and particulate matter *etc.* are generated. Particularly, the CO₂ emission from incineration varies significantly in comparison to total GHG emission in waste sectors since 1990–2015 (Fig. 6; Bogner *et al.*, 2008). The char or ash residue of Incineration usually carries toxic contaminants that make a facile entry in our food chain through aquatic bodies and other water sources. In India, usage of large and small scale incineration systems are quite familiar for MSW disposal and also in some cases a small extent of energy is recovered (United States Census Bureau, 2015).

Environment friendly waste disposal technologies with prior provision for wastes to energy recovery concepts are getting importance in India. Some technologies like Refuse-derived fuel (RDF), pyrolysis and gasification have a good efficiency in waste to energy production. In RDF, MSW are converted to pellets which act as solid fuel. These pellets are further utilised for power generation. This approach is a good attempt towards reducing the load of wastes that are dumped on landfill sites. MSW having very wide range of composition variation restricts the commercial viability of RDF (Sharholy *et al.*, 2008).

In waste to energy recovery process, Pyrolysis is considered to be an efficient thermo-chemical process where waste materials are destructed and as by-products bio-oil, gas and char is produced through application of heat. This method is generally maintained

Fig. 6 Comparison between total CO₂ emission from waste and emission from incineration. Data source: Bogner, J., Pipatti, R., Hashimoto, S., *et al.*, 2008. in an oxygen starved system but it readily generates high concentration GHGs like CO and some other toxins due to low temperature conversion (Sharholy *et al.*, 2008; Rogner *et al.*, 2007).

Greenhouse Effect and Its Impact

Global Warming has emerged as a threat to the civilized world in the last century. The developing as well as developed countries has made their significant contribution for controlling of Global Warming. The emerging GHGs as carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), hydro-fluorocarbon (HFC), perfluoro-carbon (PFC) *etc* have adverse effects such as global warming. The techno-economic growth, rapid industrialization, urban lifestyle of people has roused the level of GHGs in the atmosphere. The unburned hydrocarbons from motor vehicles, open burning of fossil fuels, also the dumping of waste materials in open land are the major sources of GHGs.

Carbon dioxide is considered to be the most common GHGs which contribute about 70% of the total heat absorption from the earth surface. Methane contributes about 20% of heat absorption of the total heat absorbed in the atmosphere. Surprisingly, the earth's atmospheric temperature has been increased about 0.4–0.8°C during the last century; the most alarming issue is that the sea water level has increased to 2 mm per year. The ecological balance and environmental purity has been drastically altered. Developed nations of western world along with Russia and China have contributed about 54% of total GHG emission in 2000. Globally emission of GHG emission has been increased about 4.2% per annum from the year 1990–2000. During this time the rapid growth in industrialization and automobile sectors had enhanced the GHG emission with a rate of 21.3% and 7.3% per annum respectively. As a result of such GHG emission and Global Warming the Earth's temperature might increase by 5.5°C by the year 2050 if not controlled properly (Sharma *et al.*, 2006).

A tentative estimation in 2004 summit suggested that the amount GHG emission is around 49 Gt CO₂ eq. CO₂, CH₄, N₂O and fluorinated gases are also contributed significantly in this total amount. In 1990 total annual emissions of GHGs is increased by 24% which further enhanced by approximately 70% from 1970 (Rogner *et al.*, 2007). Among this, CO₂ can absorb about 55% of the heat reflected from the Earth's surface. It's a major GHG contributor which can stay unaltered about 500 years in the Earth's atmosphere. From the late twentieth century the concentration of CO₂ has been increased at the rate of 1.5 ppm per annum which is an alarming fact too. In comparison to other GHGs, the generation of CO₂ increases about 77% of emissions with the rapid enhancement rate of fossil fuel combustion in 2004 (Rogner *et al.*, 2007). CH₄ is another potent GHG contributor with 18% in an average. It is even more harmful towards global warming because it obviously absorb heat 25 times more than that of CO₂ and also its sustainability in atmosphere is about 10 years. Meanwhile, presence of 8% share of N₂O becomes one of the higher GHGs contributors. Another gas causing serious Global Warming is CFC, which can absorb heat about 1500–7000 times than that of CO₂. Its concentration in atmosphere is increasing by 0.5% every year. It also causes Ozone layer depletion and remains in the atmosphere unaltered for about 100 years (Roop Ganesh, 2011).

GHG Emission in India

In India, study on the regional distribution of major contributors of CO₂ emission shows that energy sector is contributing more than half (~58%) of the total CO₂ emission. Whereas other sectors like industry and agriculture also hold significant share of

Table 8 Major CO₂ emitting countries in 2008

about 22% and 17% respectively. In comparison, waste sector is contributing only 3% in total emission. Quantitatively, in future (2020) per capita CO₂ emission in India will reach 2.1 ton and after that within 10 years that value reach approximately 3.5 ton (INCCA: Indian Network for Climate Change Assessment, 2010) (Tables 8 and 9; Climate Change status-India, 2015).

Plasma

Plasma is considered to be the fourth state of matter and it consists of neutral particles, electrons, and ions. However, as a whole it is electrically neutral (Byun *et al.*, 2010). On classifications of plasma, there are three of it: Thermal, cold and warm plasma. Thermal plasma is considered as thermally equilibrium plasma and the other is considered to be non-thermal equilibrium plasma. High temperature profile of thermal plasma indicates its efficiency towards various field of application (Gomez *et al.*, 2009; Ruj and Ghosh, 2014). Transferred and non-transferred arc torches are mainly used to generate plasma for different types of application. Non-transferred arc torch generates a high temperature plasma plume which is directly applied to the working substrate. Application of such type of torch is more generalised in various industrial applications like plasma cutting, welding, spraying *etc.* In plasma plume generation process, inside the arcing zone of plasma torch carrier gases like N₂, Ar, are transformed into plasma. The plasma arcing zone is generated between the anode and cathode gap through application of high electric potential difference. The phenomenon of arcing is quite similar in transferred torch but here the arcing zone is outside the plasma torch. Also the reacting materials act as an electronic linker between cathode and electronically grounded anode (Huang and Tang, 2007; Tang *et al.*, 2013). Some other classifications like direct current (DC)/alternating current (AC), radio frequency (RF), Microwave (MW) and DC-RF hybrid arc plasma system are also utilised as plasma generation systems (Tang *et al.*, 2013). All are considered in design and development of gasification systems. Plasma Arc driven gasification technology is one of the most emerging waste disposal technique. Owing to the high waste destruction efficiency and eminent energy recovery potential, plasma gasification is considered an emerging system of waste disposal throughout the world. Some countries have also used this technology in diverse applications.

It is found that plasma gasification generates more syn gas than the ordinary gasification and emits significantly less amount of CO₂ (Table 10; Janajreh *et al.*, 2013). The emission of SO_x, NO_x and other toxins like dioxin, furan is usual in an ordinary gasification plant. Plasma gasification holds a very low level (below permissible limit) of toxins emission (Janajreh *et al.*, 2013). Keeping the advantageous points of plasma technology, it is commercialised in various parts of the world. But in India the technology is still confined in some pilot plants in few sectors. Navreet Energy Research and Information (NERI) took the first attempt to install one plant (NERIFIER) at Nohar, Hanungarh, Rajasthan. Waste treatment rate of NERIFIER is about 50–150 kg per hour which shows its efficiency of waste destruction is about 70%–80%. Tata Energy Research Institute (TERI) gasification unit is the second plasma gasification plant in India installed at Gaul Pahari campus of Tata Energy Research Institute (TERI), New Delhi (Sharholly *et al.*, 2008).

Table 10 Comparison between plasma gasifier and ordinary gasifier

<i>Syn gas mole fraction</i>	<i>MSW gasification with ordinary gasifier</i>	<i>MSW gasification with plasma gasifier</i>
H ₂	17.04	43.50

^bHHV- Higher heating value.

Data Source: Janajreh, I., Raza, S.S., Valmundsson, A.S., 2013. Plasma gasification process: Modeling, simulation and comparison with conventional air gasification. *Energy Conversion and Management* 65, 801–809.

Plasma arc technology directed our society that MSW could be utilised as a source of renewable energy. Production of clean syn gas with very low emission of toxins validates the smooth operation and implementation of plasma arc technology for safe waste management.

Potential of Energy Recovery

Beside the organic part, combustible materials (papers, plastics, food waste, wood, textiles, disposable diapers, leather) are the larger components of MSW. It could be used as a feedstock in energy recovery. To get an idea about efficiency of MSW towards the energy recovery some parameters like carbon and nitrogen (C/N) ratio, calorific value (CV), moisture content of MSW are important. However, parameters of MSW largely depend upon the compositions, place of generation *etc.* of MSW. In India, The C/N ratio of waste ranges from 15 to 45 (Fig. 7) and the calorific value (CV) lies between 500 and 4000 kcal/kg (Fig. 8) due to wide variation in the composition of MSW. Higher extent of moisture content in MSW indicates very low energy recovery efficiency as it directly affects the heating value of MSW. Moisture content also varies widely in Indian cities (Fig. 7; *Waste Generation and Composition: Central Pollution Control Board, India, 2017*) as some places in northern India have very high moisture content in MSW and also the C/N ratio and calorific value (HCV) are comparatively high. Whereas, densely populated mega cities like Greater Mumbai, Delhi, Kolkata, Chennai, Hyderabad *etc.* have moderate range of parameters and also generating high amount of MSW. In India, Energy recovery from waste can be commercially viable approach due to considerable parameter range and huge availability feedstock. All facts show that MSW could be a potential feedstock for waste to energy recovery systems (Sharholy *et al.*, 2008).

Potential of GHG Emission Mitigation

Improper treatment of MSW can cause emission of GHGs which have high content of CH₄, CO₂, and N₂O. Generally, waste materials are improperly disposed off into land filling sites or burnt in open land without paying much attention towards environmental pollution. The most common practices like land filling, open burning are increasing day by day and as a result the extent of GHGs emission in the environment has been increased with a very high intensity. Incineration of waste also emits GHGs along with other toxins into the atmosphere (EIPPC Bureau, 2006).

Now, it is necessary to find the best possible option for GHGs mitigation especially in the field of waste disposal. Considering environmental and societal health, reduction of GHGs emission could be possible through material and energy recovery from waste. It is estimated that around 1.83×10^6 kg CO₂-eq/year could effectively be reduced by only recovering metal parts form waste. For paper waste, value of GHGs reduction is seven times higher than the recovery of metal. It's also true that every component in waste material cannot be recovered or recycled; some will remain as solid waste which could be disposed off through energy recovery pathway. The waste to energy generation process can be an alternative for traditional fuels and also it can reduce the demand of fossil fuel to some extent. The emission of GHGs could also be reduced by the application of plasma arc

Fig. 7 Indian scenario of moisture content and C/N ratio variation in India. Data Source: Waste Generation and Composition: Central Pollution Control Board, India, 2017. Available at: <http://cpcb.nic.in/waste-generation-composition/>.

Fig. 8 Calorific value variation in Indian Cities. Data Source: Waste Generation and Composition: Central Pollution Control Board, India, 2017. Available at: <http://cpcb.nic.in/waste-generation-composition/>.

gasification process and also the produced fuels like syn gas and methanol could reduce GHGs emission as compared with the burning of other conventional fuels. Moreover, waste to energy conversion concept through material recovery could be a solution to deal with the GHGs emission as well as climate change. Subsequently, plasma arc technology becomes the valuable method for safe waste management through generation of green energy with suppression in consumption of fossil fuel (Bogner *et al.*, 2008).

Plasma Arc Driven MSW Treatment Plant

A mini plant has been designed and installed at CSIR-CMERI, Durgapur for the safe disposal of MSW (Scheme 1). Waste materials are collected from different sources and then fed into the plasma hearth for its safe disposal. Two valves are put in the plasma chamber so that waste materials can be channelized properly and air can't enter into the hearth and also the produced gas cannot move out of the hearth. Plasma is being generated through three plasma electrodes placed at a star shape 120° apart in the plasma hearth for generating plasma arc. Through the transferred plasma electrode, plasma plume is generated inside the plasma hearth. The temperature generated here is about 1500–3000°C. At this higher temperature the waste materials are completely gasified and as a by-product non leachable slag is generated which is stored at the slag collector present at the bottom of plasma hearth. The waste volume reduction is about 95% and that clearly signifies that the waste materials are totally disposed and only 5% slag product remains there. The produced gas is then passed through a catalytic converter and a redox reactor through which the produced gas mixture is cleaned. Nickel catalyst is present in catalytic converter which reacts with the higher hydrocarbons present in the gas generated in plasma hearth and converts it to simplified lower hydrocarbons. If CH₄ is present in the gas coming after

Scheme 1 Process Flow diagram of MSW disposal plant.

Fig. 9 Global production of methanol by the year 2014. Data source: Methanol Market Services Asia (MMSA), 2014. Methanol, Methanol uses. The Essential Chemical Industry Online. Article, the University of York. Data adopted from Methanol Market Services Asia (MMSA); Galadima, A., Muraza, O., 2015. From synthesis gas production to methanol synthesis and potential upgrade to gasoline range hydrocarbons: A review. *Journal of Natural Gas Science and Engineering* 25, 303–316.

being treated in catalytic converter it becomes CO, CO₂ and H₂. It actually enhances the presence of syn gas as the final output of plasma treatment procedure. Carbon sieve is present in redox reactor which helps to convert steam and water vapour into CO, CO₂, and a little amount of H₂O.

After that the gaseous mixture is passed through a dry water scrubber where water is sprayed into the scrubber chamber so that the toxic gas (HCl) may get dissolved in it and a toxin free gas gets out. Then the gas is made to flow through a condenser where the temperature is lowered down by introduction of water. This gaseous mixture is then utilised for energy generation. This gas mixture mainly comprises of CO and Hydrogen (Synthetic natural gas). Because of the presence of higher contents of Synthetic natural gas or syn gas, the gas has a very high calorific value. The produced gas is used as fuel to run gas engine and also to generate electricity.

Methanol Production From Syngas

Methanol is an important chemical for industrial sectors due to its very wide range of application. In paint and pigment industry methanol act as solvent whereas in fuel cell it acts as source of hydrogen (Reubroycharoen *et al.*, 2003). In production of bio-diesel

and synthetic fuel methanol also plays an important role. In recent days, to meet the energy demand industries are looking for alternative sources of hydrocarbons. Keeping this fact, gasoline production from methanol is nowadays becoming a forefront technology in energy production sectors. Consecutively, worldwide the methanol production is considerably high (Fig. 9; Methanol Market Services Asia (MMSA), 2014) and in future the demand will increase enormously (Galadima and Muraza, 2015).

Production of methanol from syngas is a well established phenomenon and the major source of syngas is natural gas and oil. Gasification of coal in a controlled system can also produce syngas. In coming days for continuous supply of syngas we have to look for an alternative source as the conventional sources are drastically diminished (Bermúdez *et al.*, 2010). Production of syngas from MSW utilising plasma arc technology become a solution for continuous supply of syngas.

Plasma gasification can simultaneously produce syngas with drastic suppression of MSW in a safe and environment friendly way. Herein, methanol production from syngas could be commercially viable because the feedstock is MSW. Production of methanol following this path could be an aid towards “waste to wealth generation” (CanPete *et al.*, 2014).

Conclusion

Greenhouse gas emission is evident towards global warming and degradation of social and ecological balance. In relevance to this, huge accumulation of MSW and improper waste management causes serious issue to the mankind. So, there is a need of such a scientific process which could destroy waste, mitigate GHGs and also produce new sources of energy. Plasma arc driven MSW disposal system has emerged as a suitable process to fulfil these requirements. Waste to syngas generation and syngas to methanol production from waste without any harmful effects on the environment has made this technology viable. This technology is safe, easy to operate and eco-friendly. Waste to wealth recovery without harming our ecosystem is always a better option towards the sustainable development of our society.

Introduction

In the context of limited fossil resources and energy sustainability, maximum resource utilization is the possible way towards sustainable energy solution (Bundgaard *et al.*, 2017). Better utilization of energy resources gives better economic performance and reduces carbon footprint of the energy system. It also minimizes the harmful emission to the environment. Another possible way to achieve sustainable energy goal is to increase energy efficiency both in generation and in demand side. Polygeneration is an option to utilize energy resources efficiently (Jana *et al.*, 2017). By properly designed polygeneration, improved energy efficiency can be achieved. Also energy efficiency in demand side is improved due to distributed supply of utilities. In distributed polygeneration, utilities are supplied in locality. Long distance transportation and transmission is not feasible. Hence, it reduces transportation and transmission loss in demand side and increases efficiency in demand side.

Another critical challenge to the human being is global warming. Presently climate change due to global warming is an inevitable fact. Anthropogenic greenhouse gas emission is the main reason for global warming (IPCC, 2015). Country wise highest greenhouse gas emitter is shown in Fig. 1. It is noted that China, United States and India are the highest greenhouse gas emitter. Hence, many countries decided to limit the GHG emission at COP21. To reduce the CO₂ emission associated with the fossil fuel used in energy sector, carbon capture and storage (CCS) is a possible option. But significant amount of energy penalty and economic penalty is observed due to CCS. It reduces overall energy efficiency of the plant. It also requires significant economic investment. Thus, polygeneration with carbon capture and utilization (CCU) emerges as possible solution to this (Koytsoumpa *et al.*, 2018). Utilization of captured CO₂ may offset the economic penalty of CCS (Dowell *et al.*, 2017). Hence, proper system integration is required for efficient polygeneration to deliver utility efficiently. In this article, polygeneration is defined and its advantages are shown. Inputs and outputs of polygeneration along with its classification are given. Thermodynamic schematics of various utility deliveries are shown. Different parameters to assess a polygeneration are indicated in this article. Integration of CCS and CCU, possible output utilities production are mentioned along with literature survey.

Definition and Advantages of Polygeneration

To achieve the goal of 'sustainable development', resource utilization efficiency is one of the important pillars. Multi-generation or polygeneration is a designation to use input energy resources efficiently. Polygeneration is the system of integrating multiple processes to obtain multiple utility outputs through an efficient (viz. thermodynamic, economic, environmental, social) energy system by single or multiple sources of energy inputs. At the same time, maximum resource utilization reduces the carbon footprint for unit output and gives maximum utilization of materials also. On the other hand, it reduces the harmful waste to the environment.

Fig. 2 Energy cascading of heat at different temperature.

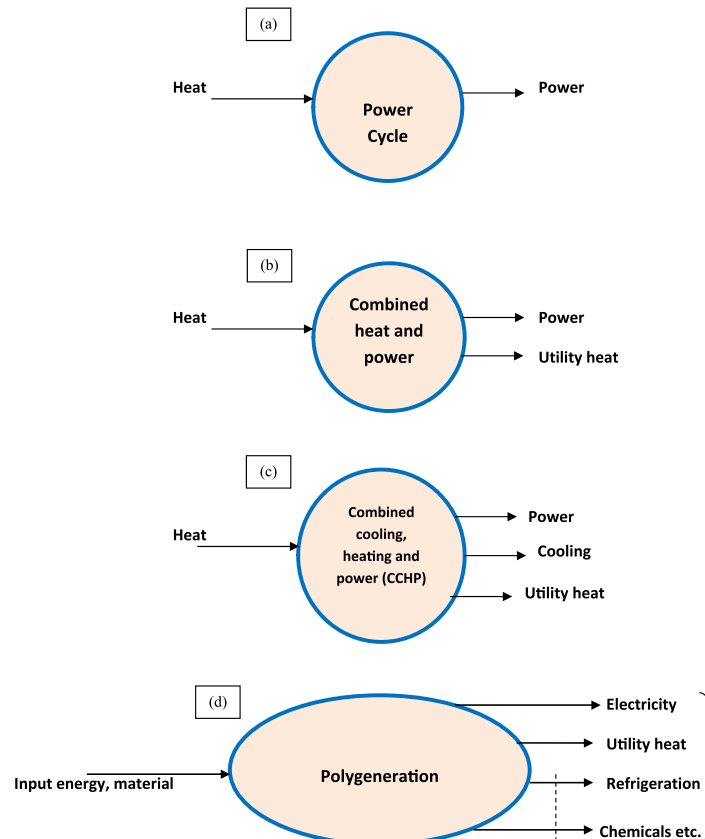

Fig. 3 (a) Power generation, (b) cogeneration, (c) trigeneration and (d) polygeneration.

Energy cascading is a thermodynamic way of getting maximum output from a definite input. It gives the opportunity to utilize heat source according to their thermodynamic quality. In energy cascading output of one energy system is the input to other downstream system as shown in Fig. 2. Fuel may be utilized directly in fuel cell or after combustion the hot flue gas may be utilized as input to the gas turbine. Then exhaust of the gas turbine may be used for steam generation in the downstream steam turbine cycle. However, low temperature flue gas may be utilized in organic Rankine cycle or in CO₂ power cycle for power generation. Several criteria have to be considered to find the suitable organic fluids for ORC including thermodynamic properties, fluid stability and chemical reactivity, safety, health and environmental hazards. Availability and costs of the fluid is also important for long run operation of ORC. Then, low temperature heat (say, at 100°C) can be used for vapor absorption cooling or water desalination process. Thus, input energy can be used by energy cascading for different utility outputs viz., power, heating, cooling, desalinated water etc.

In conventional power generation, input heat is converted to the power through different power cycles as shown in Fig. 3(a). Details of different power cycles are discussed later. In combined heat and power (CHP) or cogeneration, utility outputs are heat

and power as shown in Fig. 3(b). It increases the energy efficiency as compare to power generation only. However, along with heat and power, cooling is another utility which is produced in combined cooling, heating and power or trigeneration as shown in Fig. 3(c). Apart from power, heating, cooling, production of other utilities (say, chemicals, liquid fuels etc.) is possible by polygeneration plant as shown in Fig. 3(d).

There are several advantages of polygeneration. Some of those are- (a) it increases energy efficiency, (b) it minimizes waste, (c) gives better economic performance, (d) gives better environmental performance, (e) properly designed poly-generation increases social acceptance as it may meet the needs of local areas. However, disadvantages of polygeneration are that it increases complexity of the system and it increases inter-dependency of different sub-processes within the poly-generation. Hence, failure of one process may affect the performance of the downstream processes. Another important aspect of polygeneration is that it can be integrated with carbon capture process. The captured carbon may be utilized for other processes as discussed later.

Inputs and Outputs of Polygeneration

Inputs of a polygeneration are selected according to availability of fuel, size of the plant and desired outputs of the plant. In general, polygeneration may be classified as decentralized or centralized plants as shown in Fig. 4(a and b) respectively. The catchment area or supply area and capacity of decentralized plant is smaller. Hence, number of plants is more for a particular area as compared to centralized plant. On the other hand, capacity and supply area of centralized plant is larger as shown in Fig. 4. Centralized plant can be renewable or non-renewable energy based. However, the decentralized plan is generally renewable energy based as shown in Fig. 5. Centralized plants are always grid connected. However, decentralized plants may be on-grid, micro-grid or off-grid.

Different possible inputs to a polygeneration plant are shown in Fig. 6. For maximum utilization of coal, polygeneration is a possible option. Coal is a high energy density fuel with good source of hydrogen and carbon. Coal may be utilized through combustion or gasification of fuel. After direct combustion of coal, hot flue gas is produced and this flue gas may be used in downstream process for generation of power, heating or cooling. Coal may also be used after gasification process. In gasification process, coal is converted to syngas. This syngas may be utilized for gaseous or liquid fuels like FT fuel, dimethyl ether (DME), methanol etc. Coal based polygeneration may be integrated with carbon capture process to reduce its carbon footprint for secondary energy generation. Hence, it has the possibility to decarbonize the energy system through carbon capture and storage (CCS) or carbon capture and utilization (CCU).

Fig. 4 (a) Decentralized and (b) centralized polygeneration.

Fig. 5 Classification of polygeneration.

Fig. 6 Inputs of polygeneration.

Fig. 7 Outputs of polygeneration.

Another important fuel input to polygeneration is biomass. Similar to the coal, biomass is also solid fuel consist of hydrocarbons e.g., cellulose, ligno-cellulose. But its hydrocarbons are complex in nature. Hence, conversion of biomass is more critical due to its low conversion rate, tar formation and ash fusion. As energy density of biomass is less and it is a scattered resource, distributed polygeneration plant is preferred for biomass based plants. Biomass may be converted through thermo-chemical or bio-chemical route. Gasification, pyrolysis, torrefaction are the options for thermo-chemical conversions. In first generation biomass conversion, soyabean oil, rapeseed oil, jatropha etc were converted to bio-fuels. This challenges the 'food security'. In second generation biomass conversion, waste from wood, agriculture etc are converted to useful form of secondary energy e.g., liquid fuels, electricity etc. In third-generation biomass conversion, the rate of conversion is enhanced by improved catalysts or by improved processes. In fourth generation, carbon capture is integrated with polygeneration to get negative net-negative carbon emission. One of the greatest sources of biomass is agricultural waste. Other sources are plantation crop waste (say, coconut fiber) and waste of food processing industry (say, sugarcane bagasse).

Another important source of renewable energy is solar energy. It can also be used as input to the polygeneration. However, solar energy is hybridized with other sources of energy as its energy density is low for multi-generation. Biomass gasifier and fuel cell are mostly hybridized with solar energy for polygeneration as noted from open literature. When biomass is hybridized with fuel cell, heating, cooling and electricity are the outputs. Additional outputs like alcohols, liquid fuels etc are obtainable when solar based polygeneration is integrated with biomass. Other forms of energy like wind, geothermal etc. can also be hybridized in polygenerations. Hybridized systems help to reduce the storage capacity required for intermittent energy sources.

Polygeneration is designated to deliver multiple utilities from a single unit. Possible outputs are shown in [Fig. 7](#) as obtained from literature. Electricity is the most widely used form of secondary energy. Hence, electricity is the most significant output of a polygeneration. For centralized polygeneration, utilities are transmitted or transported. However, long distance transportation or

Fig. 8 (a) Gas turbine cycle, (b) steam turbine cycle, (c) combined cycle.

transmission is not economically feasible for decentralized polygeneration. Hence, output utilities are consumed locally and distributed polygeneration are designed to cater to the needs of local people only. Heating and cooling are other two outputs of polygeneration. Heating may be used for room heating or industrial process heating. In polygeneration cooling is generally heat driven. Waste heat available in polygeneration is used for vapor absorption cooling process. Water is another important output of polygeneration. In the present context of water scarcity and water contamination, production of drinking water is significant. Production of drinking water from naturally available water may be heat driven or power driven. In heat driven process, low

Fig. 9 Vapor absorption refrigeration.

temperature waste heat is used in multi stage flash or multi effect distillation. To control the fluctuating load (electricity) and intermittent source of energy, power driven water purification may be applied to a polygeneration.

Synthetic fuel is another important output of polygeneration. As stated earlier, biomass and coal are sources of hydrogen and carbon. In polygeneration, hydrogen and carbon are synthesized to liquid or gaseous fuel. The possible fuel outputs are ethanol, methanol, higher alcohols, DME, Fischer-Tropsch liquids etc. The production process of each fuel is different and it needs significant amount of input energy in the form of power. Integration with polygeneration increases the efficiency as compared to standalone units. Apart from fuel, polygeneration has also the capability of delivering different chemicals like ammonia, urea, etc. When polygeneration is integrated with carbon capture and utilization process, different fuels and liquids production is possible as discussed later.

Thermodynamics of Utility Production

As stated earlier, electricity is the most important utility of polygeneration. There are several energy conversion devices or prime movers for electricity generation. Fuel cell can produce electricity directly from fuel. However, it needs novel material. Impurities in input fuel should be very less for fuel cells.

Gas turbine is another energy conversion device for producing power. However, for gas turbine, input should be gaseous i.e. natural gas or derived syngas from gasification. The impurity level should be within the specified limit. The schematic of gas turbine cycle is shown in Fig. 8(a). However, micro gas turbine is also available for decentralized polygeneration. For directly fired coal or biomass, steam turbine cycle converts the input heat to power as shown in Fig. 8(b). In this cycle, steam is generated by heat of combustion of fuel. This steam is expanded through steam turbine to produce power. The steam turbine is coupled with generator to produce electricity. To increase the efficiency of gas turbine cycle, it is combined with bottoming steam turbine cycle as shown in Fig. 8(c). For decentralized power generation, internal combustion engine is a good option due to its robustness. However, the selection of this device is based on capacity, input fuels, economy etc.

Another important output of polygeneration is cooling. Cooling in polygeneration is generally heat driven. Schematic of vapor absorption refrigeration is shown in Fig. 9. In this refrigeration process, heat is the input energy at $\sim 100^{\circ}\text{C}$ to the generator of vapor absorption refrigeration cycle. The substances used may be $\text{NH}_3\text{-H}_2\text{O}$ or $\text{H}_2\text{O-LiBr}$ solution. Drinking water is another important output of polygeneration. Schematic of multi stage flash desalination is shown in Fig. 10. This is a heat driven water desalination process. Number of stage may vary from 2 to 12. Though number of staging increases the yield of water production, it also increases the economic investment. Hence, the stages are optimized according to the inputs and outputs.

Fig. 10 Multi stage flash desalination.

Performance Parameters

Assessment through analysis is important to examine the sustainability aspects of polygeneration. To be a sustainable energy solution, polygeneration should be economically feasible, socially and environmentally acceptable. Various assessment methods are there for polygeneration. Different parameters are shown in [Fig. 11](#). Thermodynamic parameters show the technological aspects and possible improvements within the process. Thermodynamic assessment is done based on 1st law and 2nd law of thermodynamics. Economic assessment shows the economic feasibility and economic benefits of the polygeneration. Several parameters like return on investment (ROI), payback period, net present value (NPV) are used for economic analysis of polygeneration. Polygeneration may be assessed by social parameters too as it should be socially acceptable. For environmental assessment, life cycle assessment (LCA) is the most scientific approach.

A few assessment parameters are given below ([Jana and De, 2015a](#)):

$$\text{energetic efficiency} = \frac{\text{energy equivalent of utility outputs}}{\text{fuel energy input} + \text{other from of energy input}} \quad (1)$$

$$\text{exergetic efficiency (energy utilization efficiency)} = \frac{\text{exergy of output utilities}}{\text{exergy of input utilities}} \quad (2)$$

$$\text{Cost utilization factor} = \frac{\text{market price of output utilities and materials}}{\text{market price of input utilities and materials}} \quad (3)$$

Fig. 11 Various bases for polygeneration assessment.

Fig. 12 Carbon capture option for polygeneration.

$$\begin{aligned}
 &\text{Usefulness of polygeneration with relative priority} \\
 &= \sum_i \left(\frac{1}{N} \times x_i \times \frac{\text{production of output utilities and materials}}{\text{demand of output utilities in the locality and materials}} \right) \\
 &x_i = \frac{(\text{price}_i \times \text{demand}_i)}{\sum_i (\text{price}_i \times \text{demand}_i)} \quad (4)
 \end{aligned}$$

$$\text{Carbon emission factor} = \frac{\text{CO}_2 \text{ emission from the polygeneration plant with CO}_2 \text{ capture}}{\text{total CO}_2 \text{ emission from individual units delivering same utilities}} \quad (5)$$

$$\text{Carbon emission factor} = \frac{\text{CO}_2 \text{ emission from the polygeneration plant with CO}_2 \text{ capture}}{\text{total CO}_2 \text{ emission from individual units delivering same utilities}} \quad (6)$$

$$\text{land or water utilization factor} = \frac{\text{land or water used in stand alone units}}{\text{land or water used in polygeneration} - \text{water produced (in case of desalination)}} \quad (7)$$

Polygeneration With Carbon Capture

In the present context of global warming, CO₂ emission reduction from the energy sector is an urgent need. There are many ways of CO₂ reduction from energy sector as observed from the literature. CO₂ capture and storage is one of the established options of carbon emission reduction. But it requires significant amount of input energy in the form of both heat and power. Hence, it reduces overall efficiency of secondary energy generation.

Integration of carbon capture with polygeneration may decrease the energy and economic penalty. Captured CO₂ in polygeneration process may be stored, or may be utilized for value added services and fuel synthesis as shown in Fig. 12. There are various options for CO₂ capture and utilization as discussed below.

Carbon Emission Reduction and Utilization Potential Through Polygeneration

In general, carbon capture process may be of three type, viz., (a) oxy-fuel combustion, (b) pre-combustion capture and (c) post-combustion capture as shown in Fig. 13. In oxy-fuel combustion process, combustion of fuel is done by oxygen only in absence of N₂. Hence, the product gas of combustion mostly contains H₂O and CO₂. By condensing the H₂O, CO₂ is separated from the

Fig. 13 (a) Oxy-fuel combustion, (b) pre-combustion CO₂ capture (c) post-combustion CO₂ capture.

product gas. But for production of oxygen from air, air separation unit (ASU) is required. The air separation process is also energy intensive. Another option for capturing CO₂ is pre-combustion capture. In this process, fuel is gasified by partial oxidation. Then water gas shift reaction is done to increase the CO₂ and H₂ contents. Then CO₂ is separated by various chemical absorption or adsorption process. Hence, this process too requires additional energy. Post-combustion CO₂ capture is another option. In this process CO₂ is separated after combustion by suitable chemical absorption process. After that it may be stored or utilized for various subsequent processes. After capturing CO₂, it may be used for value added products as shown in Fig. 14. Additional value added products increase the material utilization efficiency and minimize the waste. It also reduces and may even offset the economic penalty due to CO₂ capture. There are mostly three significant methods of CO₂ conversion as shown in Fig. 15. In photochemical process, solar radiation is used to convert CO₂ to value added products. Electricity from various renewable sources (wind, solar) is used in electrochemical process to convert CO₂ and store intermittent renewable energy in form of chemicals. In thermal process heat energy is used to convert CO₂ e.g., plasma may be used for the reduction of CO₂ to convert it to CO. Apart from chemicals and fuels, CO₂ may be used for different value added services as shown in Fig. 16. It may also be used for enhanced

Fig. 14 Schematic of carbon capture and utilization process in polygeneration.

Fig. 15 Conversion route of CO₂ to fuels and value added products. Reproduced from Hu, B., Guild, C., Suib, S.L., 2013. Thermal, electrochemical, and photochemical conversion of CO₂ to fuels and value-added products. *Journal of CO₂ Utilization* 1, 18-27.

Fig. 16 CO₂ to different value added services. Reproduced from Koytsoumpa, E.I., Berginsa, C., Kakarasa, E., 2018. The CO₂ economy: Review of CO₂ capture and reuse technologies. *Journal of Supercritical Fluids* 132, 3–16.

oil and gas recovery which increases the production of oil and gas from its reservoir. In polymer processing, urea production from CO₂ may be used as the chemical feedstock. In food processing industry, it may be used in beverages, for wine production, for horticulture etc. CO₂ may be used for algae production which is used for advanced biofuel production. Another important use of CO₂ is that it may be utilized as the working medium for different thermal processes. For power generation from low temperature waste heat, it is used in supercritical and transcritical power cycles. It can also be used as working medium for refrigeration cycle. In literature, several authors reported about CO₂ capture and storage including utilization processes. Summary of those is given in

Table 1 Summary of polygeneration with CO₂ capture and storage/utilization

Author	Inputs	Carbon capture	CO ₂ capture technology	CO ₂ captured for	Outputs

Note: Jana, K., Ray, A., Majoumerd, M.M., Assadi, M., De, S., 2017. Polygeneration as a future sustainable energy solution – A comprehensive review. *Applied Energy* 202, 88–111.

Table 1. From the table, it is noted that CO₂ capture is used for wide range of coal and biomass inputs. Rectisol, selexol, monoethanol amine are mainly used for the CO₂ capture process. Captured CO₂ may be utilized for fuel synthesis, oil recovery and storage.

Conclusion

CO₂ emission from fossil fuel (mostly coal) based power plants is the major source of greenhouse gas for climate change. Ever increasing demand of energy with population growth and improved life style has also made the problem even more complicated. With huge demand of energy worldwide and available renewable technologies, it is impossible to replace fossil fuel based systems by renewable alternatives overnight. Distributed generation with locally available renewable resources may be a good interim option for mitigating greenhouse gas and carbon footprint. Polygeneration is emerging as an efficient and decarbonized energy solution. In polygeneration, optimum system integration increases the different performances viz., thermodynamic, economic and environmental performances of the plant. Distributed polygeneration utilizing locally available resources to cater to the secondary energy and other utility needs of the local people, increases the social acceptability. Polygeneration integrated with carbon capture gives better performance than standalone carbon capture process. Also polygeneration with carbon capture and utilization emerges as the most promising option to even offset the penalty of carbon capture process.

 T_g Flue gas temperature (K)

Introduction

The rise of global average temperature due to excessive emission of greenhouse gases (specifically CO_2) due to combustion of fossil fuel is an issue of great concern for the survival of future generation. Fossil fuel based power plants are responsible for the majority of this CO_2 emission. However, fossil fuel burning is unavoidable for a considerable period to maintain a desirable industrial growth and living standard.

Though renewable power generation is increasing worldwide, the majority of the global demand for electricity is still from coal based power plants. There is a major gap between generations of secondary energy using renewable resources and corresponding global demand for a sustainable development. In this situation, replacement of older coal based power plants with an improved natural gas based power plants, retrofitting of existing low efficient power plant, incorporating CO_2 capture and sequestrations are possible options to continue with fossil fuel and simultaneously to fight against the threat of global warming. However, all of these are long term and capital intensive options.

On the other hand, a large part of all industrial energy inputs through combustion of fuels is finally released to the local atmosphere as waste heat for existing technologies. This waste heat may be utilized to produce more electricity introducing suitable technology for this purpose. Thus, the amount of fossil fuel burning required for generating an equal amount of power will be reduced and corresponding CO_2 production will be eliminated due to adoption of these waste heat recovery schemes.

It is observed in the literature that if waste heat is available above 250°C , steam based Rankine cycle is the well established technology for converting waste heat into secondary energy. Steam based CCGT (Combined Cycle Gas Turbine) may be cited as an example in this respect. However; innovation is required to generate secondary energy from waste heat available below 250°C .

Some of the refrigeration cycles are heat driven. Replacement of vapour compression refrigeration system with such low grade waste heat driven refrigeration systems will also lead to lesser fossil fuel consumption. Ejector based refrigeration cycles are capable of producing refrigeration effects using low grade waste heat even when waste heat temperature is as low as 100°C .

Due to over use and even with climate change available water for human consumption is fast decreasing. Desalination technology is an important need for future sustainability. Low grade waste heat may also be utilized for the purpose of desalination adding more sustainability. In the middle-east countries, substantial amount of drinking water is produced by the process of desalination.

Review of Energy Scenario Worldwide and Share of Fossil Fuel

Global energy consumption is ever increasing. It is reported in [International energy outlook IEO \(2017\)](#) that between 2015 and 2040 world energy consumption will increase by 28%. More than half of this increment in energy consumption will be in non-OECD Asia (including India and China) due to the rapid economic growth of these countries. It is predicted in this report that there will be 51% increment in energy demand in non-OECD Asia. In Africa and Middle East, this growth will be 51% and 45% respectively. Industrial sector that consumes more than 50% of the world energy production appears to be a major end user of global energy supply.

Though, global contributions of renewable energy are increasing sharply, fossil fuels like liquid fuel (including petroleum), coal and natural gas are the major sources that still contribute to most of the global energy demand. [World energy council/ resources, 2016 summary \(2016\)](#) that oil accounts for 32.9% of global energy demand. On the other hand, coal accounts for close to 30% of global basic energy consumption. 40% of the global secondary energy demand is by coal based power plants. Natural gas is the third major contributor to global primary and secondary energy demands. Presently it contributes to 24% of the global primary energy demand and 22% of the global electricity demand.

Impact of Fossil Fuel on Carbon Footprint

Though fossil fuel contributes to the majority of the global demand for energy, fast depleting resources of fossil fuels and greenhouse gas emissions due to the burning of these fossil fuels are two major concerns. According to [IEA Statistics \(2015\)](#), in the year 2013 global CO₂ emission due to combustion of different fuels had been 32,189.7 million tonnes. 46% of this total emission was due to combustion of coal. The corresponding share of oil and natural gas had been close to 34% and 19.8% respectively. It is critical to note that CO₂ emission due to fuel combustion in the year 2013 was 56.1% higher than that of year 1990. Sector wise, electricity and heat production together contributed to 42.4 % of Global CO₂ emission of the year 2013. Transportation sector was responsible for 23% of global CO₂ emission in that year.

To reduce CO₂ emission, various emission trading schemes have been implemented by various countries. These schemes set prices for CO₂ emission. Some of the countries introduced carbon tax, tax on fuels responsible for emission etc. Currently the EU emission trading system (ETS) includes Norway, Iceland, Liechtenstein and twenty seven members of states. However, it is projected in [International energy outlook IEO \(2017\)](#) that between 2015 and 2040 CO₂ emissions related to Coal, Oil and natural gas will increase by 0.1%, 0.7% and 1.4% respectively. These increments are appreciably small compared to the increment of CO₂ emissions observed between 1990 and 2015 – corresponding values during this period were 2.3%, 1.2% and 2.2% respectively.

It should be noted that in the year 2015, China and USA deducted CO₂ emission by 0.7% and 2.6 % respectively compared to that of 2014. However, these decrements have been nullified by 5.1% and 1.3% increment in emission by India and European Union.

Status of Renewable Energy and Gap between Demand and Supply

As discussed in the previous section, it is clear that the power sector is responsible for more than 40% of the global CO₂ emission. So instead of burning fossil fuels it is better to concentrate on renewable resources like Solar, wind, hydro power etc. Wind, solar and nuclear energy are the forms of energy that can effectively reduce global CO₂ emission. However, improved technology for large power generation at lower cost is the critical challenge for wide spread power harvesting from renewable sources.

It was reported by [IEA Statistics \(2016\)](#) that in the year 2014 only 13.8% of global primary energy was produced from Renewable resources. For electrical energy supply, corresponding value was 22.3% of global electricity production. Out of this 22.3%, 16.4% were only from hydro power and 1.8% was from bio fuel and waste. Thus, in the year 2014, only 4.1% of global demand of electricity was from geothermal, solar, wind and tidal resources.

[International energy outlook IEO \(2017\)](#) reported that between 2015 and 2040 renewable use will grow at an average rate of 2.8% per year. During this period global share of coal based power will decline from 40% in 2015 to 31% in 2040. In the year 2040, renewable resources will contribute 31% of the global demand for secondary energy. Among non hydro-power renewable resources, solar and wind are two fastest growing sectors- global capacity of these two resources will be 2.5 and 1.4 trillion kWh respectively in the year 2040. However, global electricity demand will rise from about 22 trillion kWh in 2015 to about 33 trillion kWh in 2040 and about 57% of this demand will be from coal and natural gas based power plants. Corresponding CO₂ emission will also be an issue of great concern. More over the availability of renewable resources greatly depends on location and environmental condition. Fluctuating supply of electricity from renewable resources is a great challenge for its successful utilization. Thus, in addition to the progress of renewable power generation technology other possible options are to be explored to reduce carbon footprint resulting from burning of fossil fuels. Innovation for improved utilization of fossil fuels for lower CO₂ emission appears to be critical at present.

Improved Utilization of Limited Fossil Fuel

As according to present situation, utilization of renewable resources alone cannot replace fossil fuel based power generation completely, CO₂ emission may be reduced by cutting down fossil fuel consumption with improved utilization efficiency of fossil fuel based power generation. Cogeneration, trigeneration and polygeneration are the technologies available for improved fossil fuel utilization.

Delivering two forms of energy utilities simultaneously using the same energy resource is known as cogeneration. Most widely used cogeneration systems are combined heat and power (CHP) systems in which simultaneous power and process heat are supplied from a single unit. By using a CHP system, it is possible to achieve even 80% overall energy utilization.

Tri generation delivers three utilities (say, power, process heat and refrigeration effect) from a single system. In a tri-generation system, generally an absorption-chiller is integrated with the CHP system. In the early phase of 1980s cooling, heating and power generation were integrated to form a tri-generation unit for serving the purpose of municipal cooling and heating ([Emho, 2003](#)).

When more than three energy services are combined together, the scheme is generally referred to as poly generation. For example, a desalination plant can also be integrated with production of process heat, power and refrigeration effects.

Besides improving thermal efficiency, carbon capture and storage is the direct way to reduce carbon footprint. There are three different pathways of capturing CO₂ before its storage:

- (1) Post combustion CO₂ capture: In this method CO₂ is captured after the combustion of fuel. This is a preferred technology for retrofitting of existing power plants. Larger energy penalty and higher cost are two major constraints for commercial implementation of post combustion CO₂ capture. Implementation of post combustion CO₂ capture may increase electricity generation cost even by 70% (Leung *et al.*, 2014).
- (2) Pre combustion CO₂ capture: In this method the fuel is pre-treated to remove carbon from it before the final combustion of rest combustible, mainly hydrogen. For an example, before the actual combustion of coal, a gasification process may produce a syngas, which is mainly a combination of CO and H₂. This syngas is then converted to a mixture of H₂ and CO₂ through a water gas shift reaction. High concentration of CO₂ in the mixture of CO₂ and H₂ results in better separation efficiency for absorption and adsorption. Pre combustion CO₂ capture is a suitable option that can be used for an integrated gasification combined cycle (IGCC) power plant.
- (3) Oxy fuel combustion: in this process, pure oxygen is used as the oxidant instead of air during the combustion process. This results in flue gas free from nitrogen and its oxides. Particulate matters and SO₂ are separated from the flue gas by electrostatic precipitation and desulphurization methods respectively. Finally flue gas that contains about 80%–98% CO₂ is compressed, transported and stored. Requirement of a large air separation unit results in higher costing and about 7% energy penalty (Leung *et al.*, 2014). Corrosion of equipment due to high SO₂ concentration is another issue of concern for its implementation.

After separation of CO₂ from flue gas it is to be transported to a storage site through road tanker, ship or pipeline. The pipeline is the most viable option for offshore transportation of CO₂.

Finally, CO₂ is to be stored in geological reservoir. Depleted oil and gas reservoir, un-mineable coal beds, saline aquifer are possible geological reservoirs for storage of CO₂.

As a substantial part of the energy input is finally rejected as waste heat it can be utilized to produce secondary energy or utilities that consume the secondary energy. Thus, additional requisite fuel burning for supplying this amount of electricity and corresponding CO₂ emission may be avoided.

Energy Efficiency Through Waste Heat Recovery

Most of the industrial units require thermal energy input for their operation. It was presented by Rosen (2013) that in the year 2005 total industrial energy input was about 87.6 Exa Joule (EJ). Out of this energy input only 44.6 EJ was utilized. Thus, nearly 50% of the industrial energy input remained un-utilized and ultimately released into the environment as waste heat. Obviously there is wide variation in quality and quantity of waste heat released from different industries.

Utilization of industrial waste heat to meet a part of localized electricity demand or to supply auxiliary power to run equipment may enhance overall utilization efficiency of fossil fuel input and reduce carbon footprint through less fossil fuel consumption. It should be noted that energy performance of waste heat recovery unit greatly depends on quality of waste heat and environmental condition. Proper selection of technology and suitable working fluid are also very important factors for the successful implementation of waste heat recovery process.

Classification of Waste Heat Recovery and its Challenges and Issues

It is important to note that majority of waste heat is carried away by the flue gas streams and released finally to the local atmosphere. Depending on the temperature of the waste heat, it can be classified into three different categories as shown in Table 1.

The quality of waste heat depends on flue gas temperature and can be represented by its exergy value. Exergy is the theoretically maximum useful work obtainable from a given heat source. It depends on flue gas temperature as well as the temperature of the immediate surroundings as shown in Eq. (1):

$$e_g = c_{pg}(T_g - T_0) - c_{pg} \ln \left(\frac{T_g}{T_0} \right) \quad (1)$$

Variation of exergy of flue gas stream with a varying flue gas temperature at different ambient temperatures is demonstrated in Fig. 1. It is evident from Fig. 1 that exergy or the quality of the flue gas decreases with a decrease in flue gas temperature.

Table 1 Waste heat classification

Flue gas temperature (°C)	Category waste heat	% of total global waste heat
> 300	High temperature	21
100–299	Medium temperature	16
< 100	Low temperature	63

Note: Forman, C., Muritala, I.K., Pardemann, R., Meyer, B., 2016. Estimating the global waste heat potential. *Renewable and Sustainable Energy Reviews* 57, 1568–1579.

Fig. 1 Exergy variation with varying temperature of flue gas.

The most effective way of utilizing waste heat is to produce secondary energy through some thermodynamic cycles. For fixed heat source and sink temperatures, theoretically most efficient thermodynamic cycle for generating power is Carnot cycle. As during the execution of any real cycle, certain finite temperature difference between the flue gas and the working fluid during heat transfer is always be there, the efficiency of the any actually executed cycle is always less than that of the Carnot cycle. Efficiency of any power cycle sharply decreases with a decrease in heat source temperature. As a result waste heat recovery becomes more challenging as flue gas temperature decreases. This challenge is even more for the ambient temperature being higher.

Besides flue gas temperature, composition of the flue gas is another major factor for the selection of suitable waste heat recovery scheme. If some amount of SO_2 is present in the flue gas then SO_2 reacts with moisture and produces sulphuric acid. Reaction of sulphuric acid formation is presented as follows:

Acid dew point temperature (i.e., sulphuric acid condensation temperature) of the flue gas varies between 115° and 160°C depending on the SO_2 content in the flue gas. As sulphuric acid is highly corrosive, cooling of the flue gas in the waste heat recovery unit (HRU) below the acid dew point temperature must be avoided to ensure longer life. Improving 1st law or thermal efficiency of a thermodynamic cycle is the prime objective as for a specified mass flow rate and temperature of the flue gas, waste heat available is fixed. However, if the flue gas is free from SO_2 , it is better to cool it to a much lower temperature as it would increase the power output from same available heat of the flue gas. Thus, for SO_2 free flue gas, maximizing work output per kg of flue gas flow is the objective instead of improving thermal efficiency of conversion of waste heat to work. While improving cycle performance, economical aspect must also be considered.

Need of Innovation in Low Grade Waste Heat Recovery

The technology available for converting available waste heat at a temperature higher than 250°C is well established. Steam based Rankine cycle is the best option for utilizing this heat source from thermodynamic as well as environmental point of view. Steam based Combined cycle gas turbine power plant may be cited as an example for utilizing available waste heat above 250°C . However, appreciable amount of flue gas is coming out from different industries at a temperature lower than 200°C .

Most commonly available technology for converting low grade heat into power is by using an Organic Rankine cycle (ORC). However, for subcritical ORCs at least 20° – 30°C terminal temperature difference is to be maintained at the higher temperature end of the HRU to maintain a feasible size of the HRU. This results in lower turbine inlet temperature and smaller thermal efficiency of the ORC. Generally the pinch point temperature difference occurs at the exit of the economizer as shown in Fig. 2. For maintaining the feasible size of the HRU, there should be 5° – 10°C pinch point temperature difference between the flue gas and the working fluid streams. Due to this pinch limitation of ORC, flue gas cannot be cooled below a certain temperature. This leads to a bad utilization of waste heat of flue gas free from SO_2 as the cycle power output decreases due to a smaller heat input to the cycle. Thus innovations are required to improve thermodynamic performance by addressing these two issues.

Fig. 2 Temperature profiles for working fluid and flue gas of an ORC.

Selection of Working Fluid for Low Temperature Waste Heat Recovery

Selection of suitable working fluid with zero ODP, low GWP and reasonable thermodynamic performance is another challenging task. CFCs (Chlorofluorocarbons) had been most preferred working fluids since 1930. However, Montreal protocol decided to phase out production of CFCs by 2010 due to high ozone depletion potential of CFCs. Soon HCFCs (Hydrochlorofluorocarbons) appeared as alternatives of CFCs. But due to very high GWP use of HCFCs will not be permitted after 2030 in developed countries and after 2040 in developing countries (Powell, 2002). HFCs are to be phased out by the year 2047 according to Kigali amendment to the Montreal protocol introduced in 2016. In this situation, natural refrigerants, Hydrocarbons, and some of the HFCs (Hydrofluorocarbons) with low GWP are the possible working fluids for waste heat recovery as listed in Table 2 (Calm and Hourahan, 2011).

Both CO₂ and NH₃ are in use since the 19th century. However, high toxicity of ammonia is an issue of great concern for their utilization in the HRU. On the other hand, CO₂ is a non-flammable and non toxic working fluid. Due to lower critical temperature, CO₂ at supercritical state can be utilized for the recovery of low grade waste heat. This eliminates the pinch limitation of

the subcritical HRU. Supercritical CO_2 has a concave shaped temperature profile as shown in Fig. 3. This allows operation of the HRU with smaller terminal temperature differences by maintaining a feasible size of the HRU. Thus, CO_2 can be heated closer to the flue gas inlet temperature to achieve higher 1st law efficiency. High operating pressure ($> 10\text{MPa}$) of CO_2 inside the HRU is a disadvantage of the CO_2 power cycle. However, CO_2 may be considered as the most preferable working fluid after steam if thermodynamic, environmental and safety issues are considered together. For low grade waste heat recovery, CO_2 is emerging as a better option than steam.

Hydrocarbons yield satisfactory thermodynamic performance for low temperature waste heat recovery. They are non toxic and with zero ODP and negligible GWP. However, they fall in A3 safety category which means they are highly flammable gases. Thus, possible safety measures are to be ensured to eliminate the accidental explosion while using HCs as working fluids.

HFCs are having higher GWP compared to HCs. However, they are favoured due to their excellent thermodynamic properties and less chance of explosion. For an example R32 is slightly flammable and R245fa is non flammable. But R245fa is toxic to some extent.

Besides refrigerants listed in Table 2, recently some of the HFOs (Hydrofluoroolefins) may be considered for future use as working fluids. As listed in Table 3 these working fluids are less flammable compared to hydrocarbon as well as having zero ODP and lower GWP. However, they are still not available commercially.

Finally, it should be noted that saturated vapour lines of some of the working fluids (R600, R600a, and R245fa etc.) have positive slope. These working fluids are known as dry working fluids. Some of the working fluids which are having almost vertical vapour lines are known as isentropic working fluids. With the use of dry or isentropic working fluids, compulsory requirement of a super heater in conventional ORC can be eliminated.

Some Case Studies and Current Status

Low grade waste heat recovery through innovative power cycle is recently gaining importance. According to recent studies, transcritical CO_2 power cycle, Organic flash cycle, ORC with a blend of hydrocarbon and inert compounds are possible options for the conversion of low grade waste heat (i.e., $120^\circ\text{C} < t_g < 200^\circ\text{C}$) to power. Besides vapour absorption refrigeration cycle, ejector refrigeration cycle is also emerging as another option for the utilization of low grade heat below 150°C . A few case studies for such low grade waste heat recovery are discussed here.

Fig. 4 (a) Lay out of the regenerative T-CO₂ power cycle. (b) T-s diagram of the regenerative T-CO₂ power cycle. Reproduced from Mondal, S., De, S., 2015. Transcritical CO₂ power cycle – Effects of regenerative heating using turbine bleed gas at intermediate pressure. *Energy* 87, 95–103.

Case study-1, Regenerative CO₂ power cycle – A scheme for utilization of low grade waste heat of flue gas containing SO₂ (Mondal and De, 2015)

In this study, the available flue gas temperature was 200°C and flue gas could not be cooled below 120°C in the HRU to avoid sulphuric acid condensation. Thus, in this study improvement of 1st law efficiency was the basic objective as the recoverable heat was a constant quantity for specified mass flow rate of the flue gas. To achieve higher 1st law efficiency two regenerators were introduced into the system as shown in [Fig. 4\(a\)](#). The T-s diagram of the proposed layout is presented in [Fig. 4\(b\)](#). The CO₂ stream coming out from the compressor at state-e initially was heated in the low temperature (LT) regenerator by the heat of exhaust CO₂ stream of the turbine. Then the CO₂ stream entered into the High temperature (HT) regenerator at state-f and was heated further to state-g by the heat of the bleed CO₂ stream extracted at some intermediate pressure (i.e., state-j) of turbine expansion. After being cooled (process j-k) in the HT regenerator bleed CO₂ mass was pressurized to turbine inlet pressure (i.e., state-l) and mixed with the main CO₂ stream. After the mixing, total mass of CO₂ mass was heated (i.e., process m-a) to turbine inlet temperature by the waste heat of flue gas. Various input parameters considered during the analysis are listed in [Table 4](#).

It was observed that the 1st law efficiency as well as the 2nd law efficiency increased monotonically as more and more mass of CO_2 was extracted from the turbine for the purpose of heating of the main CO_2 stream in the regenerator. With larger bleed mass of CO_2 , total CO_2 mass entered into the HRU at some higher temperature. Thus, the larger mass of CO_2 was heated in the HRU by using the same mass of flue gas as well as irreversibility of the HRU reduced with the introduction of additional regenerator. Finally, it was concluded in this study that efficiencies could not be improved beyond a certain level as an increment of bleeding CO_2 mass beyond a certain value resulted in exponential increment in the size (i.e., NTU) of the HT regenerator.

This analysis also considered the effects of varying isentropic efficiency of the compressor on cycle performance. It was observed that cycle performance improved more significantly with a higher isentropic efficiency of the compressor for higher values of bleed

Table 4 Operating condition of the regenerative T-CO₂ power cycle with turbine bleeding

Operating parameters	Values
Turbine inlet pressure	12 MPa
Turbine Inlet temperature	150°C
Turbine exit pressure	6 MPa
Flue gas inlet temperature	200°C
Isentropic efficiency of the turbine	90%

Note: Mondal, S., De, S., 2015. Transcritical CO₂ power cycle – Effects of regenerative heating using turbine bleed gas at intermediate pressure. Energy 87, 95–103.

ratio. An optimum bleed pressure corresponding to maximum 1st and 2nd law efficiency was identified during the operation of the proposed cycle for any specified bleed mass of CO₂ from the turbine.

Case study-2, a comparison between T-CO₂ cycle and Organic flash cycle (OFC) while utilizing low grade heat of flue gas free from SO₂ (Mondal and De, 2017a)

Due to the smaller thermal efficiency of power cycles driven by low grade heat sources, only larger heat input would result in satisfactory power output. Thus, if flue gas is free from SO₂, it is better to cool the flue gas down to some lower temperature to enhance power output from a given mass of flue gas available at a temperature below 200°C. Transcritical CO₂ power cycle without regeneration and Organic flash cycle (OFC) are two cycles that allow cooling of the flue gas down to a temperature which is much smaller than the acid dew point.

T-s diagrams of these two cycles are presented in Figs. 5(a) and 5(b) respectively. As shown in Fig. 5(b) in organic flash cycle working fluid undergoes a throttling process after being heated (i.e., process e-f) to saturated liquid state in the HRU. After throttling (i.e., process f-g), wet stream of working fluid enters into the vapour separator (State-g). Dry saturated vapour coming out from the separator is expanded (i.e., process a-b) in turbine to produce power output. It is important to note that selected working fluid for OFC should be a dry or isentropic working fluid.

Mondal and De conducted thermodynamic as well as economic comparison of these two cycles to explore the better option for utilizing low grade heat of flue gas free from SO₂. They considered R245fa and R600 as working fluids of OFCs taking environmental factors in consideration. In that analysis working fluids for all cycles were heated to 140°C using the waste heat of the flue gas at 150°C. The working fluid temperature at the exit of the condenser was 30°C for each of these two cycles.

It was reported that work output per kg of flue gas flow of OFCs were slightly lower compared to that of the T-CO₂ power cycle if 10°C terminal temperature difference was maintained at the low temperature end of the HRU. However, this difference reduced gradually as the terminal temperature difference at the low temperature end of the HRU increased gradually.

As maximum operating pressure of the T-CO₂ power cycle was much higher compared that of the OFC, the economic comparison of these cycles in terms of bare module cost (BMC) per kW of power output were also required. The analysis revealed that the T-CO₂ power cycle could produce unit power output at smaller BMC compared to that of the OFCs for 10°C terminal temperature difference at the low temperature end of the HRU. However, BMC kW⁻¹ could be reduced appreciably for OFCs by increasing the terminal temperature difference at the low temperature end of the HRU. It was concluded that T-CO₂ power cycle would be a better option for low grade waste heat recovery if thermodynamic and environmental issues are only taken into consideration. However, OFCs appeared to be an economically better option if lesser work output per kg of flue gas is acceptable. Out of OFCs, OFC with R600 was a better option due to smaller GWP of R600. However, it was suggested to take suitable safety precautions to avoid possible accident due to the high flammability of R600.

Case study-3, low grade heat recovery from SO₂ free flue gas through ejector base combined power refrigeration cycle (Mondal and De, 2017b)

Organic flash cycle (OFC) is capable of converting low grade waste heat into power effectively if flue gas is free from SO₂. However, in an OFC, appreciable amount of energy remains un-utilized due to throttling of saturated liquid stream exiting the vapour separator.

Mondal and De proposed to utilize the energy of this saturated liquid stream to run an ejector based refrigeration cycle as shown in Fig. 6. Saturated liquid stream exiting the vapour separator entered as the primary flow to the ejector. Saturated vapour stream leaving the refrigerator evaporator entered into the ejector as the secondary flow.

The ratio between the secondary mass flow and the primary mass flow was maintained in such a manner that the total refrigerant mass leaving the ejector was at condenser pressure. R245fa was considered as the working fluid due to zero ODP and non-flammable nature. This cycle exhibited appreciably higher first and second law efficiency compared to an ordinary OFC. For condenser temperature more than 40°C, an additional compressor was introduced into the system for achieving reasonable amount of refrigeration effect.

Fig. 5 (a) T-s diagram of T-CO₂ power cycle. (b) T-s diagram of OFC. Reproduced from Mondal, S., De, S., 2017a. Power by waste heat recovery from low temperature industrial flue gas by Organic Flash Cycle (OFC) and Transcritical-CO₂ power cycle: A comparative study through combined thermodynamic and economic analysis. Energy 121, 832–840.

Case study-4. Desalination using low grade heat source (Hamieh *et al.*, 2001)

Hamieh *et al.* (2001) demonstrated desalination of mild brackish water containing about 800 PPM of dissolved solids. They applied dew evaporation technique for this purpose – this device could be operated even when the heat source temperature is in between 65° to 100°C.

The working principle of the dew evaporation technique may be explained with the help of Fig. 7. The dew evaporation system consists of an evaporation tower and a dew formation tower. In the evaporation tower, air is allowed to pass from bottom to top and saline water is allowed to come down through the wall of the tower at some higher temperature. The air absorbs the water and comes out through the top portion with high moisture content. The air is further heated before entering into the dew formation tower and humidified to increase humidity. While coming down through dew formation tower, air is cooled and dehumidified by

Fig. 6 Layout of ejector based combined power and refrigeration cycle. Reproduced from Mondal, S., De, S., 2017b. Ejector based organic flash combined power and refrigeration cycle (EBOFCP&RC) – A scheme for low grade waste heat recovery. *Energy* 134, 638–648.

Fig. 7 Heat driven dew evaporation system. Reproduced from Hamieh, B.M., Beckman, J.R., Ybarra, M.D., 2001. Brackish and seawater desalination using a 20 ft² dewvaporation tower. *Desalination* 140, 217–226.

rejecting heat to air and water passing through the evaporation tower. Fresh water getting separated from the air is collected at the bottom of the dew formation tower.

Most of the heat driven desalination system suffers from the problem of formation of scales on the heat transfer wall. The experimental setup developed by Hamieh *et al.* (2001) not only eliminated this problem, but also was capable of producing desalinated water with an energy reuse factor of 11. Energy reuse factor is defined as energy recovered by re-circulating the brine to that of supplied from the external source.

Conclusions

As CO₂ emission due to fossil fuel combustion is mainly responsible for global warming, it is necessary to reduce global consumption of fossil fuel. However, global consumption of primary and secondary energy is increasing steadily with time. Though technologies of

producing power from renewable sources like solar, wind, geothermal, etc. are improving; still there is an enormous gap between global demand of secondary energy and installed capacity of power from renewable resources. As more than 50% of the industrial energy input as heat remains unutilized and finally rejected to atmosphere as waste heat, utilization of this waste heat for producing power and other energy utilities may be a significant sustainable options for reducing global carbon footprint.

Technology for producing power using high temperature (i.e., above 250°C) industrial waste heat is a well established. However, this conversion becomes very challenging as the waste heat temperature is below 200°C. Suitable working fluid selection based on thermodynamic, environmental and safety issues together is another challenging task. CO₂ may be considered as the most suitable working fluid for low grade waste heat recovery if thermodynamic performance, safety issues and environmental issues are preferred aspects.

In this article, four case studies are reported to explore possible ways of utilizing low grade waste heat of available industrial flue gases. The first case study illustrates suitability of CO₂ power cycle for utilization of low grade waste heat of flue gas containing SO₂. In the second case study it was demonstrated that CO₂ power cycle without regeneration as well as OFC were effective to convert low grade SO₂ free waste heat into power. In the third case study working principle of a low grade waste heat driven combined power and refrigeration cycle was demonstrated. In the fourth case study, possible use of low grade waste heat driven dew evaporation desalination system was explored. The temperature of this waste heat was as low as 100°C. These case studies demonstrate that there is a huge potential of effective utilization of low grade waste heat for producing power and other energy services adding to lesser consumption of fossil fuel and corresponding lower CO₂ emission for same energy services. However, further research is necessary for commercial utilization of low grade waste heat for producing power and other energy utilities.

Introduction

Cleaner manufacturing plays a vital role in the day to day life of mankind, it is a continuous preventive environmental strategy applied to processes, products and services to increase overall efficiency, and reduce risks to humans and the environment. Cleaner production can be functional to the processes used in any industry, to products and to various services provided in society. The mission of cleaner production can be achieved from preserving raw materials and energy, replacing toxic/hazardous materials and reducing the quantity and/or toxicity of all emissions and wastes before they leave a production process (see “Relevant Websites” section). The manufacturing industry aim should be to improve productivity and product quality at the same time as maintaining clean and sustainable environment (Aghion *et al.*, 2009). Environment awareness is of the utmost importance to all socially responsible manufacturers. A strict environmental regulation has to be regulated into the industry keeping increasing global competition in the world. The change in environment are indicated through CO₂ emissions per capita, change in forest area, consumption of ozone depleting substances, and lack of access to improved sources of water (Ayouty *et al.*, 2017). The automobile industry is under pressure to take action at its product carbon footprint. The wide use of fossil fuels is gradually more renowned as unsustainable as a result of depletion of supplies and the input of these fuels to climate change by GHG (greenhouse gas) emissions into the atmosphere (Maity *et al.*, 2014). It is very important to understand that the future of industry depends upon how we channelized today (Aghion *et al.*, 2009), therefore mitigation of greenhouse gases can only be achieved by adopting sustainable techniques of manufacturing which include minimizing the number of manufacturing steps by employing advanced and alternative methods (Gupta *et al.*, 2016). Increased energy efficiency, optimization of energy structure and the generation of a sustainable consumption and production patterns will provide opportunities to resolve regional and the global environmental problems (Yia *et al.*, 2007). With the increasing report on environment and energy shortage, the world have understood the importance of its prevention, therefore this task of promoting education in energy conservation and environment effect has been taken actively. Many countries have started to identify their responsibility for decreasing the unfavorable effect of high energy use on the environment (Bilgen and Sankaya, 2018). Most of the industry are examining the flow of materials and energy in a company and tries to identify options to minimize waste and emissions out of industrial processes through source reduction strategies. For better selection in use of materials and energy, and to avoid waste, waste water generation, and gaseous emissions, and also waste heat and noise the development of organization, technology and ethics of company should be correct which will help in mitigation of greenhouse gases (see “Relevant Websites” section). Waste Management and consumption patterns will continue to be important activities for many years to come (Kjaerheim, 2005) (Figs. 1–3).

The Evolution of Cleaner Manufacturing

The concept of clean manufacturing was developed under the leadership of Jacqueline Aloisi de Lardere, the former Assistant Executive Director of UNEP, during the preparation of the Rio Summit as a programme of UNEP (United Nations Environmental Programme) and UNIDO (United Nations Industrial Development Organization). The programme was meant to reduce the environmental impact of industry. It built on ideas used by 3 M (Man, Machine and Material) in its 3P programme (Pollution Prevention and Pays). It has found more international support than all other comparable programmes. The programme idea was describe to assist developing nations to progress from pollution to less pollution using available technologies. Clean production was developed with simple idea to increase the resource efficiency of production by less waste. UNIDO has been operating National Cleaner Production Centers and Programmes (NCPCs/NCPPs) with centers in Latin America, Africa, Asia and Europe (see “Relevant Websites” section). At first, productivity improvement focused only on quantity; i.e., outputs. As the markets developed and competition increased, cost effectiveness became the key factor towards success. Therefore, a cost reduction approach was used to improve profitability or organizational effectiveness; viz. productivity. Next, growing consumer preferences and competition lead in the era of the quality drive. The consistency of delivering the utmost quantity of a product at the desired level of quality in a cost-effective manner became the third generation concept in the productivity movement and hence a number of management systems emerged – Total Quality Management (TQM), Total Preventive Maintenance (TPM) and subsequently, the international standard on Quality Systems viz. the ISO 9000 series. While the productivity concept expanded, the field of environmental management also matured and broadened (see “Relevant Websites” section) (Table 1).

Fig. 1 Definition of clean manufacturing.

Fig. 2 Tracking the influence of quality programmes on productivity (<http://www.unep.fr/shared/publications/other> – How to establish and operate cleaner production centres).

Fig. 3 Categories of manufacturing unit. Reproduced from Anon, Applying cleaner production to multilateral environmental agreements. Basics of cleaner production.

Table 1 Environmental impacts linked with manufacturing waste

<i>Waste type</i>	<i>Environmental impact</i>
Defects	Raw materials consumed in making defective products, defective components require recycling or disposal. More space required for rework and repair, increasing energy use for heating, cooling, and lighting
Waiting	Potential material spoilage or component damage causing waste. Wasted energy from heating, cooling, and lighting during production downtime.
Overproduction	More raw materials consumed in making the unneeded products Extra products may spoil or become obsolete requiring disposal.
Movement and transportation	More energy use for transport Emissions from transport More space required for work-in-process (WIP) movement, increasing lighting, heating, and cooling demand and energy consumption. More packaging required to protect components during movement.
Inventory	More packaging to store WIP Waste from deterioration or damage to stored WIP More materials needed to replace damaged WIP More energy used to heat, cool, and light inventory space.
Complexity and over processing	More parts and raw materials consumed per unit of production, Unnecessary processing increases wastes, energy use, and emissions.
Unused creativity	Fewer suggestions of pollution and waste minimization opportunities.

Components of Clean Manufacturing

The six main components of CM are:

- **Waste Reduction:** the term waste refers to all types of waste including both hazardous and solid waste, liquid and gaseous wastes, waste heat, etc. The goal of CM is to achieve zero waste discharge.
- **Non-Polluting Production:** Ideal production processes, within the concept of CM, take place in a closed loop with zero contaminant release (no greenhouse gases or harmful products which endangers the environment).
- **Production Energy Efficiency:** CM requires the highest levels of energy efficiency and conservation. Energy efficiency is determined by the highest ratio of energy consumption to product output. Energy conservation, on the other hand, refers to the reduction of energy usage.
- **Safe and Healthy Work Environments:** CM strives to minimize the risks of workers in order to make the workplace a cleaner, safer, and healthier environment.
- **Environmentally Sound Products:** The final product and all marketable by-products should be as environmentally appropriate as possible. Health and environmental factors must be addressed at the earliest point of product and process design and must be considered over the full product life-cycle, from production through use and disposal.
- **Environmentally Sound Packaging.** Product packaging should be minimized wherever possible. Where packaging is necessary to protect the product, to market the product, or to facilitate ease of consumption, it should be as environmentally appropriate as possible (Kjaerheim, 2005).

Benefits of Clean Manufacturing

- The benefits of cleaner production comprises lessen waste, the improvement of valuable by-products, enhanced environmental performance, better resource productivity, increased efficiency, minimized energy consumption, reduces greenhouse gases and an overall reduction in costs (see "Relevant Websites" section).
- Clean manufacturing reduces operation costs for example, the costs involved with waste treatment, storage, and disposal are often reduced and the savings can be used to counterbalance the development and implementation costs of the program.
- It helps to save the raw material and refining operations which will decrease the ecological damage, and also reduces the risk of emissions during the production process and during recycling, treatment, and disposal operations.
- Clean manufacturing not only reduces effects but also enhanced company image and reputation. It improves the working environment in the organization; employees are likely to feel more positive toward their company when they recognize that management is committed to providing a safe working environment (Kjaerheim, 2005).

Clean Manufacturing Techniques

- **Change input materials:** substituting toxic or harmful materials with less toxic, employ of renewable materials, use of materials with longer lifetime and material purification.
- **Technology change:** by replacing, equipment modification, optimal process conditions, increased automation, improve process control and improve equipment layout.

- Improve operation practices: Product scheduling, energy management, maintenance programmes, working instructions and procedure, training and incentive program, adequate process control operations, proper maintenance and cleaning.
- Production Modifications: recycling friendly design, product life extension, more efficient, less material intensive packaging and reducing of harmful substances.
- On-site reuse and recycling: On-site revival and re-use of raw materials in the process, waste water, waste cooling water, converting waste into useful by-production waste segregation and storage.

Barriers to Clean Manufacturing Implementation

- Internal barriers: Low awareness of CEOs, internal constraints in organization and communication, Limited information, lack of data and knowledge on waste and emissions, Focus on short term profits by a industry, in the race of cost/profit calculations somewhere clean manufacturing options is missing, obsolete or untrustworthy process instrumentation, no or inadequate support of middle management, to achieve persistent there is no proper Environment Management System (EMS).
- External barriers: Availability of investment capital, Availability of clean manufacturing technologies and lack of effective government policies (Anon).

Clean Manufacturing Strategies

It is not sufficient to observe and decrease the residuals and emissions from the machining processes, in order to provide assurance for clean manufacturing process in the future it is essential to scrutinize and solve the core issues which increases unwanted residuals and emissions and their sources have to be identified and eliminated. A further possibility for the improvement of the environmental impact in manufacturing is through the development and introduction of new technologies as a replacement for the traditional technologies examples using machine like new cutting tool materials, rapid prototyping, laser machining, etc. keeping in the view that new technologies do not lead to environmental contamination of a different nature. Fig. 4 shows the strategies for clean manufacturing process.

- Raising awareness of environment-related activities at the facility and providing training. A training program should include all levels of personnel within the organization. The goal of such training is to make every employee aware of waste generation, its impact on the site and the environment, and ways waste can be reduced, pollution prevented, mitigation of greenhouse gases and cleaner production achieved. Provide ongoing staff education programmes, make clean manufacturing awareness program a part of new employee orientation.
- R&D, engineering, productions, strategy, the environmental department and top management all of them should re-enforced together. The discharge of carbon dioxide (CO₂) and other greenhouse gases (GHGs) due to human action is rising global

Present <i>Residual, emission from manufacturing.</i> <i>-Evaluation</i> <i>-Minimisation</i> <i>-Disposal</i> SYMPTOMS	Current status <i>Significant deficit in the consideration of effects of manufacturing processes on the environment</i>	Future <i>Clean manufacturing process in order to minimized eliminate negative environmental effects</i> CORE
Research Objectives: - Deficit elimination - Process Understanding - Environmentally friendly factory		

Fig. 4 Strategy for clean manufacturing process.

average surface air temperatures, disrupting weather patterns, and acidifying the ocean. Unawareness and ignores could cause global average temperatures to increase by another 4°C or more by 2100 and by 1.5–2 times as much in many midcontinent and far northern locations (Obama, 2017). Perseverance of top management, the development of a long-term technology strategy (25–50 years), and the integration of environmental management in business activities is especially important for accomplishment of more essential cleaner technologies. The Research and Development department should be more involved in the laying down of long-term technology strategies.

- Formation of inter-firm knowledge networks. At least three or more manufacturing firms work together in joint research projects. These joint research projects are especially productive in the pre-competitive stage. Relations between firms should be prepared to include mutual education and training, risk sharing agreements and joint agreement on performance measurements.
- Offer financial and technical incentives. Recognizing an individual's efforts in the field of clean production. Recognition of effort is also a powerful tool in maintaining a clean production program. Coordinating environmental policy incentives programmes.
- Provide public outreach and education about clean production advantages, Submit press release on innovations to local media and to industry journals read by prospective clients, arrange for employees to speak publicly about clean manufacturing measures in schools and civic organizations.
- Governments could directly interfere in the existing polluting production process by imposing more strict environmental legislation. Stimulation of government-industry partnerships. The government could introduce incentives or subsidy to the industry to encourage cleaner technology development (see "Relevant Websites" section) (Moors *et al.*, 2005; Sarkis, 1995).

Clean Manufacturing Tools

- Value Stream Map (VSM) can be used as a tool for mapping and identifying environmental impacts in the processes of the plant layout. It demonstrates the linked processes for making a family of products, from the raw material to the shipping to the customers. Below each process there is a data box which contains the environmental impacts of the process.
- The implementation of 5S in a company has an environmental impact in a positive way. 5S is usually ordered by five precise steps. These steps are: separating, setting in order, shining and cleaning up, standardizing and sustaining. By means of 5S, the companies initiate a specific identification of the different kinds of garbage using extremely visible and identifiable bins. Each bin is coded with different color and it is positioned in a precise area bounded by colored strips on the ground. In order to avoid movements of the operators the bins are placed close to the workplace.
- Cellular manufacturing is a clean manufacturing tool which has huge impact in enhancing environment performance. In cellular manufacturing methods the workplaces, machine and staff are grouped in a single cell which work in a similar products, which is arranged in a particular U-shape rather than having them in random places of the plant layout. The workplaces and machines in the cell are positioned very close to one another to save space and time. The handling and transportation of materials can, in this way, be easily reduced, which automatically affect environmental impacts in a positive way.
- Total Productive Maintenance (TPM) is cleaning and maintenance practices in an industry, which again helps to improve environment impacts. Its main intention is to keep all equipments in top functioning condition to avoid breakdowns and delays in manufacturing processes. It is managed at two important levels. Operators every day have to clean the machine and perform basic maintenance such as topping up oil levels, cleaning filters and checking pressure, temperature, and so on of the machine. It reduces the atmosphere emissions in terms of dusts and fumes (Chiarini, 2014).

Environmental Management Systems

International standardized Environmental Management Systems (EMS) should be implemented to construct a systematic environmental plan. In present condition it has become more and more important for different companies all over the world (Ljungberg, 2007; Graedel and Allenby, 1995). Actually EMSs can normally be considered as a voluntary system. Environment Management system can be seen as a tool for management that can be used to guide and control environmental efforts by computer controlling or performed by a particular organization. All company that has taken steps towards environmental concern has in fact implemented an EMS (Coglianese and Nash, 2001). There are five main mechanism of an EMS: Environmental Policy, Planning, Implementation and Operation; Checking and Corrective Action; and Management review (see "Relevant Websites" section). In an organization the Environment Management System is designed to achieve environmental goals, manage environmental issues, and continually improve environmental performance (Fig. 5).

It was World Business Council for Sustainable Development (WBCSD) during 1990s issued a statement about the relationship between environmental protection, economic growth and fulfillment of human needs (Schmidheiny, 1992). The statement has a huge impact and later there was an establishment of an international standard ISO 14001, which was released in 1996 by the International Standardization for Organization (ISO) in Switzerland (Graedel and Allenby, 1995). ISO 14000 consists of a entire series of environmental standards based on the 14001 standard (Sheldon, 1997). ISO 14001 is one of the corner stone and most well recognized standard of the ISO 14000 series. It is the only ISO 14000 standard against which it is currently possible to be certified by an external certification authority (see "Relevant Websites" section). It is important to note that the EMS as per ISO 14001 does not itself affirm specific environmental performance criteria.

Fig. 5 Environment management system model (<http://www.unep.fr/shared/publications/other> – How to establish and operate cleaner production centres).

Some of the benefits of an EMS are improved control and efficiency, reliable regulatory compliance, reduced environmental liabilities, easier access to loans, enhanced corporate image, reduced insurance premiums. An environmental policy should have the following characteristics such as suitable to nature, scale, and environmental impacts, provides framework for setting and evaluation of environmental objectives and targets; documentation, implementation procedure, maintenance procedure, and communication to all employees available to the public (see “Relevant Websites” section).

Cleaner Manufacturing in India

Clean Manufacturing has been put into practice across various industrial sectors in India. We know that growing population and rapid economic development in India has tarnished the environment, exhausted the resources + – and harshly spoiled the ecosystem. So to meet both the environmental and economic challenges, India understand the requirement for clean manufacturing and progress has been made through framing various eco-friendly policies (Manju and Sagar, 2017). The first systematic investigations, Project DESIRE was introduced for waste minimization along with pollution prevention for developing countries, it was implemented between 1993–1995, through this project it was come to know that many companies like textile and paper industries had a drastic improvement in environment performance (Unnikrishnan and Hegde, 2007). It reduces heat consumption in the range of 25%–44%, electricity consumption 5%–34%, wastewater volume 39%–41% and chemical oxygen demand 39%–51% (Berkel, 2004). In the garment sector cleaner technologies it helps to eliminate redundant washes, substitution of hazardous chemicals, water consumption and energy consumption leading to lot of benefits (Venkatesan and Scott, 2001).

The UNIDO has started national and regional cleaner production centers in India. The basic premise of the UNIDO/UNEP NCPC programme believes that sustainability of clean manufacturing is only possible if the country have right intention and capacity to adopt it. It can be successful if it is promoted by professionals by taking advantages of the local conditions. To achieve that many centre are build, which provides training and advise their clients on how to find the best solution for their specific problems rather than ready-made solutions (Ralph and Jaroslav, 2004). Important activities of the cleaner production centers (CPCs) are to provide training under capacity building. It provides in-depth modular training as well as short courses on different topics related to clean manufacturing. Most of the Courses were designed mainly for company staff and consultants, still some specific courses were also targeted towards policy makers (Unnikrishnan and Hegde, 2007). Through many case studies we can say that in India is contributing to improve the environment by implementing the clean manufacturing policies and many cooperate is also tie-up with certain such organization to improve the environment in positive way.

Conclusion

This review article outlines the overall aspects of environment and clean manufacturing as a whole. It focuses on the relationship between the quality of the environment and clean manufacturing industries and the mission of cleaner manufacturing and how it can be achieved. It helps to understand the affect of different types of manufacturing waste to the ecological balance of the environment. Article gave brief knowledge about the six main components of CM and also discuss about the benefits of CM implementation. In order to provide assurance for clean manufacturing process in the future it is essential to scrutinize and solve the core issues which increase unwanted residuals and emissions of greenhouse gases and carbon footprint, their sources have to

be identified and eliminated. This article has discussed about the strategies of identification and elimination of core issues and how different types of tools of CM helps to achieve the objectives. The CM process had a vital role to play in keeping the environment safe by mitigating of greenhouse gases in coming future. The mitigation of greenhouse gases is only be achieved by adopting sustainable techniques of manufacturing. This article also discussed about the EMS and its advantage of implementation.

For implementing national and international policies/strategies it is very important to measure and report their Carbon Footprint (CF) aimed at mitigating and adapting the environmental concerns. The information given in this article will contribute to improve environment policies for a more clean and sustainable future. As policy has an important role in supporting energy conservation in any society because not only can it produce an adequate economic environment that finally leads to savings, but it may also impose regulations for proper energy management, promote recycling and energy recovery, and encourage suitable education of the society.

Reducing Greenhouse Gas Emission From Waste Landfill

Rena, Shashi Arya, Digambar Chavan, Sadaf Aiman, and Sunil Kumar, CSIR-National Environmental Engineering Research Institute, Nagpur, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The rampant increase of municipal solid waste (MSW) along with rapid population growth, urbanization, and improper waste management options has created an unavoidable situation in the whole world. The economic prosperity and socio-economic development is the index for the rate of waste generation. Therefore, it is evident from the fact that the whole world is experiencing a high rate of a waste generation with the rapid unplanned urbanization of the cities and towns (<http://dx.doi.org/10.1080/23311843.2016.1139434>). The increased income and advanced living standard of people have considerably augmented the average waste generation rate of 0.5 Kg or g per person/day (https://www.worldenergy.org/wpcontent/uploads/2013/10/WER_2013_7b_Waste_to_Energy.pdf). Landfill gas from waste contains a high concentration of methane, which has about 30 times higher global warming impact compared to carbon dioxide (Pawlowski *et al.*, 1996). Anthropogenic sources account for 70% of total annual Methane (CH_4) (Pawlowski *et al.*, 1996), emission from rice fields, domestic ruminants, agricultural, biomass burning in the tropics, organic waste in the sewage system and landfills, fossil fuels production, transportation and utilization (Bousquet *et al.*, 2006). Fossil fuel energy is responsible for about 37% of human-caused CH_4 emissions (Tubiello *et al.*, 2014). MSW landfills are among the third largest anthropogenic sources of methane emission. Sanitary landfill is an engineered, in-ground facility for the safe and secure disposal of waste (<https://www.epa.nsw.gov.au/publications/waste/solid-waste-landfill-g259uidelines-160>) designed to reduce environmental hazards and ensures to protect human health. However, MSW at landfills has measured to be one of the major contributors to anthropogenic GHG emission and a key component in global warming (<https://www.ipcc.ch/meetings/session12/twelfth-session-report.pdf>). Landfills are supposed to produce the pollution streams, such as leachate, storm water runoff, LFG, offensive odor, dust, noise and litter thereby degrading the quality of surrounding surface water bodies, groundwater, soil, and air. Majority of MSW both in the US and globally is placed in landfills. As per the estimate US, alone releases around 92.7 MMT of CO_2 equivalents to the atmosphere in 2016 (<https://www.epa.nsw.gov.au/publications/waste/solid-waste-landfill-g259uidelines-160>). In developed countries, well designed sanitary landfills are used which typically include well-lined bottoms for leachate collection and treatment systems, gas collection, and its treatment, final covers, and air and water monitoring systems (<https://www.regulations.gov/document?D=EPA-HQ-OAR-2003-0215-0045>). Landfill undergoes in a sequence of complex physical, chemical and biological processes that lead to waste degradation. However, the process that occurs at the landfill is a natural though it can be either triggered or altered by controlling internal conditions in a landfill. The waste received at the landfill consists a large fraction of organic wastes like paper, food and green wastes that undergo degradation under anaerobic conditions and produces LFG including 50% CH_4 , 50% CO_2 and non-methane organic compounds. The existing landfills, i.e., open dumps, conventional landfill, and landfills with low-organic-waste along with adopted technologies and processes depict the amount of GHG emissions into the environment (Manfredi *et al.*, 2009). The major contributors are the direct emissions from the landfill that account to 1000 kg CO_2 -eq tonne^{-1} for the open dump (Manfredi *et al.*, 2009), 300 kg CO_2 -eq tonne^{-1} for conventional landfilling and 70 kg CO_2 -eq tonne^{-1} for low-organic-waste (Manfredi *et al.*, 2009). However, the methane generation largely depends on various factors, such as the amount of waste being received at the landfill, concerning its age, its physicochemical characteristics, including its biodegradability, and other abiotic factors, such as topography, climate, rainfall patterns, and humidity.

Hence, more sustainable and feasible methods are required to be addressed for alleviating the CH_4 emissions into the environment, through an enhanced degree of CH_4 oxidation in the landfill cover soil, and it can be achieved by optimizing the oxidation process in landfill based on parameters, such as the depth of soil cover, pH, and gas circulation coefficient.

Brief Introduction to the Landfill

A trend of significant increase worldwide has been observed in waste generation due to factors including high population growth rate, industrialization, urbanization and other. According to the report of World Bank on solid waste management, the worlds' cities generated 1.3 billion tonnes of solid waste per year amounting to a footprint of 1.2 kilograms per person per day in 2012 which is expected to rise to 2.2 billion tonnes by 2025 (<http://www.worldbank.org/en/topic/urbandevelopment/brief/solid-waste-management>). The landfill has remained as the oldest and the most common treatment method of waste disposal throughout the globe. It is an area of land that is specifically allocated for controlled disposal of waste on or beneath the surface of land with the aim of isolating the waste from the surrounding environment.

With the realization of the detrimental effects of past waste handling methods, sustainable waste management is gaining more and more attention. It emphasizes more on reducing, reusing and recycling waste and considers landfill disposal of waste as the least preferred option. All types of waste treatment options have a certain amount of residue that requires to be disposed of in a landfill. Thus, landfill persists as the primary means of waste disposal method. It also has the advantage of being the most economical option for managing waste. Landfills in use can be broadly classified in two ways, i.e., by engineering facilities

Fig. 1 Classification of landfill.

Table 1 CH₄ & CO₂ emissions and GWF as estimated using IPCC guidelines

Landfill types	CH ₄ (kg CO ₂ per tonne w/w)	CO ₂ (kg CO ₂ per tonne w/w)	GWF(LFG) (kg CO ₂ -eq per tonne w/w)
Open dump (mixed waste)	27.5–38.5	61.9–86.6	561–786
Conventional landfill (mixed waste)	2.3–13.1	85.3–228.2	– 69 to 162
Engineered landfill (mixed waste)	2.3–13.1	85.3–228.2	– 74 to 26
Engineered landfill (low organic waste)	0.8–3.0	24.7–54.2	– 48 to – 3

Note: Manfredi, S., Tonini, D., Christensen, T. H., Scharff, H., 2009. Landfilling of waste: Accounting of greenhouse gases and global warming contributions. Waste Management & Research 27 (8), 825–836.

employed (Tchobanoglous *et al.*, 1993) or by the type of waste disposed of (US EPA, 1995). Fig. 1 shows the classification of the landfill.

The major contributors of environmental pollution from a landfill are the landfill leachate and gas. Landfill leachate is the percolating water that reaches the waste due to precipitation, irrigation and to some extent, water that is generated from the waste of the landfill resulting in a liquid consisting suspended solids, soluble components of the waste and degradation products of the waste due to microbial activity. The composition and amount of the leachate will highly depend on the site conditions, heterogeneity, and composition of the waste, and, the stage of fermentation reached by the waste, the moisture content and the operational procedures. The various pollutants in leachate can be (Kjeldsen *et al.*, 2002), dissolved organic material (COD and TOC, volatile fatty acids and fulvic and humic-like material), inorganic macro-components (like calcium, magnesium, sodium, potassium, ammonium, iron, manganese, chloride, sulphate and bicarbonate compounds), heavy metals (cadmium, chromium, copper, lead, nickel, zinc) and compounds not degraded by organisms (aromatic hydrocarbons, pesticides, plasticizers, chlorinated aliphatic compounds, etc.). Several studies have reported that ammonia, chloride, acidity or alkalinity and heavy metal concentrations highly contribute to landfill leachate toxicity. Toxic leachates from solid waste landfill sites may also be mutagenic and carcinogenic (Kjeldsen *et al.*, 2002). Leachate collection and removal systems (LCRS) are incorporated in landfills for collecting the leachate and employing leachate treatment and management technologies like leachate recirculation, evaporation, neutralization (Warith, 2003), activated carbon adsorption process (Foo and Hameed, 2009), etc.

LFG emission is the other major environmental concern associated with landfill waste disposal method. Due to anaerobic conditions prevailing underneath, the biological degradation of biodegradable waste components produces LFGs. The quality and quantity of gas produced depend on the characteristics of waste, aerobic/anaerobic conditions and site conditions like pH, moisture, temperature, etc. Among others, methane and carbon dioxide contribute to 90% of total LFG (El-Fadel *et al.*, 1997). CH₄ from landfills represents 12% of total global methane emissions (El-Fadel *et al.*, 1997). Total European emissions are about 2% of the total GHG of 5000 Million ton per year (EEA, 2009). In the US, landfills are the main source of CH₄ emissions and emitted nearly 37% of total US carbon emissions in 1997 (EPA, 1999).

The greenhouse gases GHG emissions from landfills have been estimated using IPCC guidelines, 2006 considering 1 tonne of waste for 100 years (Manfredi *et al.*, 2009). **Table 1** provides an insight into the individual CH₄ and CO₂ emissions and Global warming factor (GWF) for landfill gases from various landfill types (Manfredi *et al.*, 2009).

Many efforts have been made to mitigate the CH₄ from the landfill.

About GHG Emission

Emission of GHGs from conventional waste practices in the developing countries contributed considerably to global warming. GHG emissions from waste management activities such as waste handling & processing, operational activities, and transportation are contributed indirectly especially due to fossil fuel consumption. Also, there are many possibilities for indirect GHG emissions from materials and energy use. Unfortunately, municipalities responsible for municipal solid waste management (MSWM) do not recognize the link between waste management and GHG emission.

Since many, decade's management of waste has been only correlated with human health and sanitation. GHG emission linked with the waste handling and disposal practices was recognized as a burning issue in the last few years only, before that it was not considered as a major issue in the context of global warming (Singh *et al.*, 2018).

Municipal solid waste (MSW) has been identified as a significant contributor to global warming because of GHG emissions from each of the functional waste management system. The rise in average global temperature due to GHG emissions has altered the global climatic pattern and created a threat to human and animal health. GHGs have distorted global temperature pattern & negatively affected the global environment (Singh *et al.*, 2018).

MSW is considered as the 3rd largest anthropogenic source of CH₄ emissions; it contributes to about 11% of total CH₄ emissions all over the globe (Stocker *et al.*, 2013). CH₄ emitted from landfills is identified as major contributors to GHGs. CH₄ has twenty-eight times more global warming potential than that of CO₂ on a horizon of 100 years' period (Stocker *et al.*, 2013).

Over the last decades, the concentration of CH₄ in the atmosphere has more than doubled (Sunarto *et al.*, 2017). Fast growth in industrial development and rise in population have increased the potential anthropogenic CH₄ emissions (Sunarto *et al.*, 2017). Waste disposed into landfills undergoes aerobic decomposition, which produces a considerable amount of CH₄ (Singh *et al.*, 2018; Chynoweth *et al.*, 2001).

Waste treatment or disposal approach through landfilling is most common and is expected to increase in low and middle countries. Their many alternatives are identified for open landfills such as aerob landfills, pre-composting, and energy recovery, but all these options also emit GHG emissions.

Complexity in the quantification of indirect GHGs emission from waste management sector has become a general problem. GHG emission has a strong correlation with per capita waste generation and economic development. All functional aspects of MSWM system, such as waste generation, segregation, collection, handling, storage, transfer and transport, treatment and final disposal emits GHGs both directly and indirectly (Singh *et al.*, 2018).

Developing economy and advancement in urban cities have led to a rise in a solid waste generation, and landfill waste quantity and subsequently increased GHGs emission. Therefore, quantification of CH₄ emissions from MSW landfills is a need of the hour. Studies reported that the developmental and industrial activities caused an accumulation of GHGs in the overall environment. GHG emissions are quantified during manufacturing of products, but also related to its end-of-life phase, i.e., waste treatment processes. All over the globe, emissions from solid waste disposal sites are responsible for about 3%–4% of anthropogenic GHG emissions (https://www.ipcc-nggip.iges.or.jp/public/2006gl/pdf/5_Volume5/V5_3_Ch3_SWDS.pdf). Solid waste management has been getting importance in the global GHG emissions scene.

Several studies revealed that MSW is a major contributor to GHGs through biological waste decomposition.

General sources of GHG emission from waste management sector

- CH₄ from anaerobic decomposition of organic waste.
- CO₂ from fossil fuel combustion and electricity consumption (Indirect source of emission from waste management activities).
- Nitrous Oxide (N₂O) from leachate treatment.

Summary of GHE of Different Countries (Sector Wise)

Tables 2–15 presents a summary of GHE of different countries from 1990 to 2016.

Table 2 Change in GHG emissions/reductions from 1990 to 2016: Austria

Name	Name of the sources	Amount (%)
Austria	Energy	– 47.45
	Energy industries	– 54.03
	Fugitive emissions from the fuel	– 31.73
	Agriculture	– 115.39
	Waste	– 38.53

**Fig. 2** Showing general mitigation step to reduce GHEs.

GHE Reduction Through the Different Treatment Options

Waste management sector has great potential for GHG reduction and climate change mitigation. Waste management sector can considerably contribute to the national GHG emission reduction targets. At present, GHGs, emission and global warming is a burning issue for people all over the globe (<http://www.unep.or.jp/ietc/Publications/spc/Waste&ClimateChange/Waste&ClimateChange.pdf>). The rate of fossil fuel consumption & industrialization has been accelerated for many decades which has caused a rise in earth average temperature (http://www.grida.no/graphicslib/detail/contribution-from-waste-to-climate-change_1033). As an outcome, additional methods or tools are anticipated in the waste management sector to mitigate GHG emissions, especially for new emerging economies. **Fig. 2** shows the steps required to mitigate GHG.

The general concept of capturing CH_4 and reducing GHE is not much benefit as a collection of CH_4 does not occur over the complete duration of emission generated by anaerobic decomposition (<https://www.americanprogress.org/issues/green/reports/2013/04/17/60712/energy-from-waste-can-help-curb-greenhouse-gas-emissions/>). The methane gas is not collected immediately, thus, only a fraction of gas is being trapped and EPA's waste reduction Model reports that on an average only 34% of CH_4 is being

recovered which in turn produces electricity, 38% of CH₄ emission is used for flare in a landfill, rest 28% of methane released into the atmosphere. Thus, only 62% of CH₄ is being captured and hence to reduce GHE from landfills, it is more beneficial to divert the waste to different treatment options available to treat waste (<https://www.americanprogress.org/issues/green/reports/2013/04/17/60712/energy-from-waste-can-help-curb-greenhouse-gas-emissions/>).

The quantity of GHE from a variety of solid waste treatment processes highly depends upon the type of treatment used, the distance between waste collection and waste treatment site & physical composition of waste to be treated. Decentralized waste treatment processes have less GHG emission due to onsite treatment without any transportation, less energy consumption and on-site use of end products. It indicates that the choice of the method for waste treatment process plays a vital role in reducing GHE (<https://www.americanprogress.org/issues/green/reports/2013/04/17/60712/energy-from-waste-can-help-curb-greenhouse-gas-emissions/>).

Therefore, selection of appropriate solid waste treatment process is very important to reduce the load of MSW along with the reduction of GHE for mitigating global warming (Yuan *et al.*, 2012). Integrated strategies involving recycling, composting, waste-to-energy combustion and landfills with gas collection and energy recovery play a significant role in reducing GHG emissions by recovering materials and energy from the MSW stream.

GHE Reduction Potential of Composting

Solid waste treatment through the composting process has been well established in developing countries. Most of the municipalities prefer composting for MSW treatment because it is very simple and cost-effective. The end product from solid waste composting can be used as an organic fertilizer, which is having a huge potential for reduction of GHG emission. One tone of compost from solid waste treatment can be used as a replacement for chemical fertilizer. Along with this, solid waste treatment through the composting process can reduce a load of organic waste from waste dumping sites and can minimize associated GHE by avoiding the organic waste decomposition in landfills.

GHE Reduction Potential of Anaerobic Digestion

Solid waste treatment through anaerobic digestion (AD) is also having great potential for the treatment of biodegradable waste. Among the biological treatment methods, the AD is the most popular and economical due to its cost-benefits. Biogas generated from bio-methanation of solid waste contains high calorific value & heat energy. Biogas generated from anaerobic digestion of solid waste can produce a major quantity of electrical energy. The energy generated from the AD process can be used as an alternative for conventional energy sources, and thereby solid waste can contribute to lowering GHG emission. The AD can also reduce the quantity of biodegradable waste going to landfills and thereby reduces associated GHGs emission.

GHE Reduction Potential of Mechanical Biological Treatment (MBT)

MBT has been commonly utilized as a preliminary solid waste treatment or before final waste disposal. MBT reduces the total waste quantity by biological decomposition of organic waste and ultimately reduces the GHG emission. MBT can reduce GHGs in several ways. According to composting or anaerobic digestion, MBT can reduce the quantity of organic waste from landfilling and lowers the associated GHG emissions that would otherwise occur during the decomposition of biodegradable waste in landfills.

GHE Reduction Potential of Incineration

Solid waste treatment through incineration has been extensively used all over the globe. It has reported that more than 130 million tons of MSWs are treated annually in an around 600 incineration plants (Themelis, 2003). As compared to conventional landfilling incineration reduces the GHG emission by avoiding CH₄ emissions from the landfills. Huge of the amount of electricity and steam generated in the incineration plant can be used as an alternative for fossil fuels. Additionally, incineration plant reduced the transportation of MSW to the distant landfill sites and associated GHGs emission (Kaplan *et al.*, 2009; Weitz *et al.*, 2002; Hefa and Yuanan, 2010; http://ledsgp.org/wp-content/uploads/09/User_Manual_for_GHG-waste-calculator.pdf).

Compared to the option of landfilling, WTE can curb the contribution of MSW on GHG emissions by avoiding the release of methane from landfills and offsetting emissions from fossil fuel power plants. In a comparative study of incineration and landfilling of solid waste, it has been observed that incineration process can reduce up to 1.3 tons of CO₂ equivalent emission per ton of waste by avoiding CH₄ emission from convention landfills.

EPA has reported that every 1 ton of processed garbage reduces approximately 1 ton of CO₂ emissions (<https://www.americanprogress.org/issues/green/reports/2013/04/17/60712/energy-from-waste-can-help-curb-greenhouse-gas-emissions/>). This happens because each treatment options forbid the amount of GHE emission. The recyclable are segregated and are recycled which is another benefit of using treatment options also the electricity generated through waste offsets the GHG emissions which generate from burning coal or natural gas.

Case Studies of Landfill Mitigation Programs

Ulsan Landfill Site

Ulsan is a fully successful pilot project under Climate Technology Partnership (CTP) and has been operating for nearly four years. The methane gas recovery system at Ulsan is designed to capture the gas from the landfill and transport it to local industrial sites where it is burned in boilers without being purified. The Ulsan landfill gas facility reduces GHG emissions, offsets natural gas as a fuel source and builds Korea's capabilities to install similar projects (<https://www.nrel.gov/docs/fy07osti/40428.pdf>).

Fresno Municipal Sanitary Landfill

The Sanitary Landfill in the United States named Fresno Municipal Sanitary Landfill opened in Fresno, California in 1937 is the first modern engineered sanitary landfill. It is designated as a National Historic Landmark though involving the innovating techniques, such as compacting, daily coverage of waste with soil and trenching. It underlies the importance of waste disposal in urban society (<https://cumulis.epa.gov/supercpad/cursites/csinfo.cfm?id=0901854>).

Massachusetts Municipalities

It has turned their towns and communities waste burden through proper assessment and closing their old landfills into a rehabilitated settlement for their respective communities:

The town, located north of Boston, has obtained a long-term layout for reclamation of the existing landfill site into useful areas such as business park containing a hotel, two office buildings and a sports/country club complex concerning the landfill closure. The municipality also rehabilitated one more community located at 10 miles to the west of Boston that was found for open space and recreational fields (<https://corporate.findlaw.com/law-library/landfill-closure-and-redevelopment-three-case-studies.html>). The landfill was procured with an aim to develop the landfill into wetlands and sports field. In a predicament with closure activities, the town also coupled to figure out the associated issues with the reclamation of landfill site including the transformation of the existing drainage system within the landfill site followed by new drainage construction around the landfill site (<https://corporate.findlaw.com/law-library/landfill-closure-and-redevelopment-three-case-studies.html>).

Ghazipur Landfill Delhi

"The Ghazipur Landfill is one of the biggest and oldest landfill areas of Delhi with continuous and indiscriminate MSW disposal since last 34 years (Ranjan *et al.*, 2014). Various strategies have been undertaken to minimize and reduce the negative impacts of landfill gas emissions from the landfill area. As the study reported methane and nitrous oxide were analyzed in Ghazipur landfill area (Ranjan *et al.*, 2014). However, the landfill area was converted into waste to energy plant, where the garbage was mined to convert refuse derived fuel (RDF) to be used for energy generation and ten acres of landfill area supposed to handover to Gas Authority of India (GAI) for mining methane and other gases to be used as fuel. Estimations done at field explored that the methane generated during summer was highest, i.e., 264 mg/m² h and concluded that the emitted gas has large enough calorific value that could be utilized to generate electricity" (Ranjan *et al.*, 2014).

Landfill Regulations and Program Related to GHG Mitigation

The amount of GHG emission is rising day by day. To control the emission of enormous GHG from waste landfill certain protocol, act and projects are formulated to resolve the issue. To achieve the purpose United Nations, a Climate Change conference under the framework of the United Nations Framework Convention on Climate Change (UNFCCC) hold annual Conference of Parties (COP) to implement and reviews the issues of GHG emissions. The very first COP came into force in the year 1995. Since then various meeting held which is listed below (<https://www.epa.gov/laws-regulations/summary-clean-air-act>).

- 1995: COP 1, Berlin, Germany
- 1996: COP 2, Geneva, Switzerland
- 1997: COP 3, Kyoto, Japan
- 1998: COP 4, Buenos Aires, Argentina
- 1999: COP 5, Bonn, Germany
- 2000: COP 6, The Hague, Netherlands
- 2001: COP 7, Marrakech, Morocco
- 2002: COP 8, New Delhi, India

- 2003: COP 9, Milan, Italy
- 2004: COP 10, Buenos Aires, Argentina
- 2005: COP 11/ CMP 1, Montreal, Canada
- 2006: COP12/CMP 2, Nairobi, Kenya
- 2007: COP 13/CMP 3, Bali, Indonesia
- 2008: COP 14/CMP 4, Poznan, Poland
- 2009: COP 15/ CMP 5, Bali, Indonesia
- 2010: COP 16/CMP 6, Cancun, Mexico
- 2011: COP 17/ CMP 7, Durban, South Africa
- 2012: COP 18/CMP 8, Doha, Qatar
- 2013: COP 19/CMP 9, Warsaw, Poland
- 2014: COP 20/CMP 10, Lima, Peru
- 2015: COP 21/ CMP 11, Paris, France
- 2016: COP 22/ CMP 12/ CMA 1–1, Marrakech, Morocco
- 2017: COP 23/CMP 13/ CMA 1–2, Bonn, Germany
- 2018: COP 24/CMP 14/ CMA 1–3, Katowice, Poland

For a landfill, there are specific regulations designed by USEPA (<https://www.epa.gov/laws-regulations/summary-clean-air-act>). Also, there are certain programs and projects which is used to reduce GHG emissions.

Clean Air Act (CAA)

To protect the environment and to ensure a sound public health CAA regulations were framed. It is a set of comprehensive federal law that regulates air emission from stationary and mobile source (<https://www.epa.gov/laws-regulations/summary-clean-air-act>).

EPA Rules for GHE

Municipal solid waste landfills: New source performance standards (NSPS) (<https://www.epa.gov/stationary-sources-air-pollution/municipal-solid-waste-landfills-new-source-performance-standards>)

- This rule came into force in 1991 after a series of the amendment in different year final updated rule came in the year 2016. This regulation focused on the reduction of methane emission from new modified and reconstructed MSW landfill which is rich in methane gas. It is formulated guidelines to reduce emission from existing MSW landfill (<https://www.epa.gov/stationary-sources-air-pollution/municipal-solid-waste-landfills-national-emission-standards>).

Municipal solid waste landfill: National emission standards for hazardous air pollutants (NESHAP) (<https://www.epa.gov/stationary-sources-air-pollution/municipal-solid-waste-landfills-national-emission-standards>)

- This rule was proposed in the year 2000 and focusses on the same principle of emission guidelines and new performance standards (EG/NSPS).
- The update rule came in the year 2006. This result focusses on the hazardous air pollutant (HAP) which is generated from the landfill along with CH₄ and CO₂.
- To collect and control LFG.
- Collection and control system.
- It also checks semi-annual compliance reporting (<https://www.epa.gov/stationary-sources-air-pollution/municipal-solid-waste-landfills-national-emission-standards>).

Neshap for internal combustion engine (<https://www.epa.gov/stationary-engines/national-emission-standards-hazardous-air-pollutants-reciprocating-internal-0>; <https://www.gpo.gov/fdsys/pkg/FR-2013-01-30/pdf/2013-01288.pdf>; <https://www.gpo.gov/fdsys/pkg/FR-2014-08-15/pdf/2014-19062.pdf>)

This rule came into force in the year 2004. After several amendments, EPA finalized the amendment in the regulation. The final decision and reconsideration came in the year 2014.

This rules specifically focusses on the LFG-fired internal combustion engines at major and area resources of hazardous emissions. This regulation provides measurement system performance specifications and sampling protocol to ensure reliable data.

This regulation also has guidelines for the measurement system, data recorders, electrochemical cell, moisture removal system calibration and standardization.

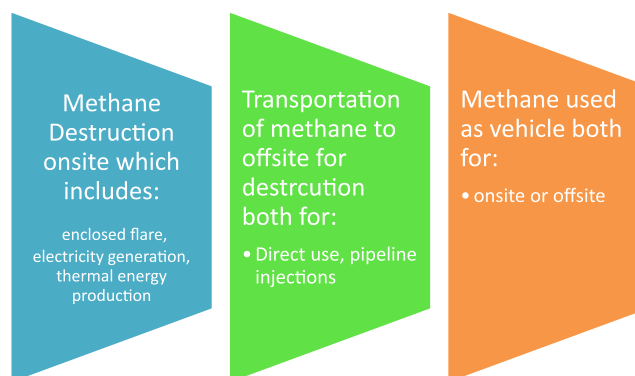

Fig. 3 Boundaries United States Landfill Project Protocol V4.0. Reproduced from Available at: <http://www.climateactionreserve.org/how/protocols/us-landfill/> (accessed 12.06.18).

Industrial, commercial and industrial boilers and process heaters: National emission standards for hazardous air pollutants (NESHAP) for major sources (<https://www.epa.gov/stationary-sources-air-pollution/industrial-commercial-and-institutional-boilers-and-process-heaters>; <https://www.epa.gov/stationary-sources-air-pollution/industrial-commercial-and-institutional-boilers-and-process-0>)

The rule was proposed in the year 2003. This rule is articulated mainly for major sources such as industrial boilers, commercial and institutional boilers which emit hazardous air pollutants. This rule has certain guidelines for LFGs collection and distribution system which are as:

- (1) The firing unit which is either infrequent in operation or works at very low-temperature loads is subjected to tune-up the practice.
- (2) The fire gas stream should be within limits and should maintain the emission limit of Hydrochloric acid (HCL), Mercury (Hg), and Carbon Monoxide (CO) as set up by the EPA.
- (3) The gas which is generated should meet the minimum methane content criterion also the heating value should not exceed the maximum mercury concentration.

Protocol Related to Landfill GHG (United States Landfill Project Protol V4.0) (<http://www.climateactionreserve.org/how/protocols/us-landfill/>)

This protocol is formulated for installation of a system used for capturing and destroying methane gas emitted from U.S landfill. This protocol includes a wide range of boundaries depicted in **Fig. 3**.

Project eligibility criteria: United States Landfill Project Protocol V4.0 (<http://www.climateactionreserve.org/how/protocols/us-landfill/>)

Compliances are considered for sanctioning any project under United States Landfill project Protol V4.0 is shown in **Fig. 4**.

Performance standard

The compliances of Performance standard of United States Landfill Project Protocol V4.0. is shown in **Fig. 5**.

Project exclusions

Projects extrusions of United States Landfill Project Protol V4.0 is shown in **Fig. 6**.

Landfill Methane Outreach Program (LMOP) (<https://www.epa.gov/lmop/basic-information-about-landfill-gas>)

To reduce the emission of CH₄ from landfill EPA has formulated the Landfill Methane Outreach Program (LMOP). **Fig. 7** shows different activities of LMOP.

Programs Related to GHG Emissions

There are certain programs which are formulated to reduce GHG emissions. Some of the programs are listed below:

Canada and Chile collaborative program to reduce GHGs emission from landfill (<http://www.ccacoalition.org/en/news/Canada-chile-join-forces-reduce-greenhouse-gas-emissions-landfills>)

Canada and Chile join forces to support clean innovation which reduces the methane emissions from landfills. Its based on bilateral co-operation formulated to deliver significant direct environmental and health issues and help Chile to use LFG as an alternative clean energy source. The project is running from 2017 and estimated to be completed by 2021.

Fig. 4 Compliances of the project under the United States Landfill Project Protocol V4.0. Reproduced from Available at: <http://www.climateactionreserve.org/how/protocols/us-landfill/> (accessed 12.06.18).

Fig. 5 A performance standard of United States Landfill Project Protocol V4.0. Reproduced from Available at: <http://www.climateactionreserve.org/how/protocols/us-landfill/> (accessed 12.06.18).

India GHG programme (<http://www.indiaghgp.org/>)

This program was launched in July 2013 by founding member companies viz., World Energy Institute (WRI), The Energy Resources Institute (TERI), and the Confederation of Indian Industry (CII).

The aim and scope of this program are to deal with assists large-scale reduction of emission and also to mitigate the Impacts of climate change.

The effort of this program is depicted in Fig. 8.

There are certain arrays of service of this program. It is listed in Fig. 9.

Landfill Gas Projects and Energy Projects Worldwide

To establish long-term success with end users, the landfill owners and operators ensure contractual agreements for the sale of LFG, electricity and other attributes generated by landfill an energy project that relies on financial side for these agreements. Hence, the

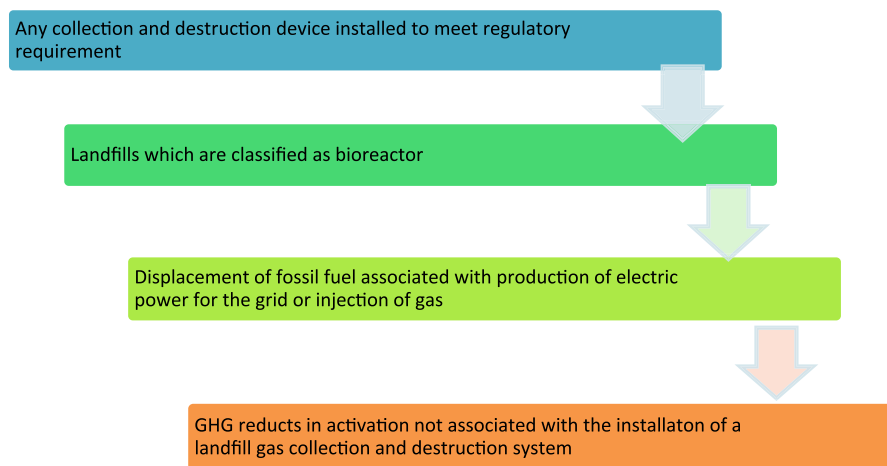

Fig. 6 Compliance of the Project Exclusions United States Landfill Project Protocol V4.0. Reproduced from Available at: <http://www.climateactionreserve.org/how/protocols/us-landfill/> (accessed 12.06.18).

LMOP includes the following activities:

Fig. 7 Different activities of LMOP. Reproduced from Available at: <https://www.epa.gov/lmop/basic-information-about-landfill-gas> (accessed 12.06.18).

Fig. 8 The Effort of India GHG programme. Reproduced from Available at: <http://www.indiaghgp.org/> (accessed 10.06.18).

owners and LFG project developers require immense information and knowledge to implement or lay out the elements of LFG contractual agreements. The different categories of the contacts are presented in **Table 16**.

LFG projects are aimed towards generating energy and reduced CH_4 emissions also, embark to bring positive outcomes for all and sundry. It also creates a partnership among citizens, NGOs, ULB's, government, and industrial partners. However, **Fig. 10** shows the LFG projects are significant and have potential benefits regarding energy, economy, and environment.

Fig. 9 Arrays of India GHG programme. Reproduced from Available at: <http://www.indiaghgp.org/> (accessed 10.06.18).

Table 16 Different categories of the contacts

Landfill gas regulations and contracts

Power sales agreements	Landfill purchase agreement	Environmental attribute agreements	Regulations and permitting
Power purchase agreement with an Investor Owned Utilities	Direct use sales of medium-Btu LFG	Direct environmental attributes i.e., destruction of methane (a potent GHG emission)	Applicable Clean Air Act (CAA) regulations
Power sales contract to a power marketer or whole sale buyer	LFG sales to an electrical generation project	Indirect environmental attributes i.e., displacement of fossil fuel use by LFG use, a renewable energy resource	Applicable Resource Conservation and Recovery Act (RCRA) regulations
Selling directly into market	High Btu sales		National Pollutant Discharge Elimination System Permit
Net metering			Applicable Clean Water Act (CWA) regulations

(https://www.epa.gov/sites/production/files/2016-11/documents/pdh_full.pdf)

Note: Available at: https://www.epa.gov/sites/production/files/2016-11/documents/pdh_full.pdf (accessed 13.06.18).

The solid waste landfills in the US are regulated by the Environmental Protection Agency (EPA) and other states environmental agencies. The regulatory authorities are aimed for safe and sound s SWM through the technical framework, monitoring, compliance, regulations, and enforcement to protect the environment from toxins that might be present in the waste. It also ensures the restriction in the entry of some banned materials from the disposal of hazardous wastes. It ensures that all the landfills envisages complying with federal regulations in 40 CFR Part 258 and are designed to protect human health and environment by controlling the emissions at the landfill. Some of the key features of the federal regulations include: setting buffer zones, for waste landfills, mandating the requirements for composite liners requirement, leachate collection and removal systems, operating practices, groundwater monitoring, closure, and post-closure care equipment. The landfill regulations in India is facilitated through Central Pollution Control Board (CPCB) that ensures the guidelines for the urban local bodies (ULB's) in dropping the nuisance value of waste management along with to enhance the aesthetic appeal. To reduce the negative impact of landfills on public health and environment, the CPCB has come out with guideline that ensures to maintain the buffer zones including a 10 m green belt around the landfill sites specified that the selected plant species should be fast growing, have a thick canopy, perennial and evergreen and act as high CO₂ sink, thereby contributing on the reduced GHG emissions, such as, Babul, Shisham, Australian babul, Neem, Jamun and Karanj.

Landfill Gas Energy Projects

To convert LFG into usable energy form, the projects are grouped into three categories: Electricity generation, Direct Use of Medium-Btu Gas and Upgraded LFG. **Table 17** shows landfill gas energy projects.

Technology: Turbines, micro-turbines, and fuel cells.

Reciprocating engine Gas turbines: Used, while micro-turbines.

Fig. 10 LFG projects and their significant benefits.

Table 17 Landfill gas energy projects

Type	Technology	Comments
Electricity Generation: ¾ of LFG generates electricity from existing LFG projects in the US	Reciprocating internal combustion engines It is most commonly used technology for converting LFG to electricity due to its relatively low cost, high efficiency and size ranges complementing the gas output of many landfills. Turbines are used in larger LFG energy projects Microturbines are applicable for smaller LFG volumes and in niche applications.	Several Combined Heat and Power (CHP) under LFG projects have been installed to convert LFG to generate both electricity and thermal energy in the form of steam or hot water using the technologies.
Direct use of Medium-Btu Gas replaces the use of another fuel like natural gas or fossil fuel, and it occurs between 1/4th of currently operational projects	The LFG produced here is piped directly to the customer	It is used directly in various industrial applications such as boiler, dryer, kiln, etc., as a substitute for other fuel consumption. It is also used to evaporate the landfill leachate
Upgraded LFG It ensures the production of equivalent pipeline-quality gas (natural gas), compressed natural gas (CNG) or Liquefied Natural Gas (LNG)	High upgraded- Btu LFG through the treatment process by the reverse mechanism of increased methane content and reduced CO ₂ , nitrogen and oxygen content.	Used as CNG or LNG in Vehicles itself at landfill sites

Note: Available at: https://www.epa.gov/sites/production/files/2016-11/documents/pdh_full.pdf (accessed 13.06.18).

Feasibility of Using LFG as a Liquefied Natural Gas (LNG) Source for the Heavy-Duty Trucks Operating Landfills in Texas

Acrion Technologies Inc. in association with Mack Trucks Inc. developed a technology to generate LNG from the gases at landfills using CO₂ WASHTM Process. The process is successfully implemented at the Eco-Complex in Burlington County, PA, in which two refuse trucks were operated for 600 h each using LNG produced from the landfill (Zeitmans *et al.*, 2008).

Landfill Gas Capture and Utilization Project at VEOLIA Environmental Services

It is a division of employs nearly 83,000 staffs operating in 35 countries around the world specialized in the management, treatment, and disposal of waste including recycling, reclamation and reuse of waste products. In 2006, the project at Veolia Environmental Services avoided 23% emissions in the volume of direct GHG emissions. It converted the CH₄ generated from landfills as a useful commodity in Thermal Energy and Electricity form. The services have ensured the LFG utilization projects at various sites as shown in Table 18.

Table 18 Landfill gas projects

<i>Site</i>	<i>Technology</i>	<i>Benefits</i>	<i>Reference</i> (http://siteresources.worldbank.org/INTUWM/Resources/340232-1208964677407/Veolia_4-9-08.pdf)
Brazil: SASA Landfill	Leachate evaporator treats up to 19 m ³ /day of leachate using LFG as fuel for the evaporator	First registered project and carbon transaction developed as a clean development mechanism and ensured reduced GHG emission at 700,000 t CO ₂ e over ten years	Tremembé Landfill Brazil
US: Cranberry Creek Landfill, USA	Direct use compressed, filtered and dried LFG is conveyed from the landfill to the plant through a 2.4 km pipeline, i.e., the methane gas from the pipeline powers the Ocean spray's steam boilers, that the energize the cranberry concentrator	Reduced GHG emissions, i.e., 6300 tonnes a year significantly reduced fuel costs by 25% at Ocean spray achievement: the site was awarded GOLD STAR AWARD from SWANA (Solid Waste Association of North America)	Cranberry Creek Landfill Wisconsin, USA
China: Xingfeng Landfill	Two 970 kW is reciprocating engines/gensets for electricity production thereby adding additional modular units with increased landfill gas.	Alleviate electricity shortage developed as clean development mechanism and reduced methane emissions	Xingfeng Landfill, Guangzhou, China
France REP, Energie	Combined cycle in 2005 nominated under French Government for renewable energy project from Biomass/Biogas to meet European Union Target i.e., 11 MW 9300 N m ³ LFG/h recovered further extended its efficiency to total 25 MW 17,000 N m ³ LFG/hr recovered since 2006	Reduced GHG emissions 74,000 tonnes CO ₂ avoided emissions reduced fuel consumption 16,400 tonnes saved. The installed capacity of 25 MW is equivalent to the consumption of 80,000 inhabitants	REP Landfill, Claye Souilly France
Greentree Landfill USA	Pipeline Quality Conversion of landfill gas (17,000 m ³ /h) into natural gas	Reduced GHG emissions green energy produced as electricity equivalent of 40 MW and is enough to satisfy the needs of 45,000 homes	Greentree Landfill, Pennsylvania, USA

Conclusions and Perspectives

Disposal of MSW being practiced all across the world leads to continues emission of GHGs and ultimately to climate change and global warming. Climate change has accelerated the need to find measures to reduce and manage the waste being disposed at landfill sites. The Challenges associated with mitigating the GHG emanating from landfills have sought to be a mammoth task, especially methane. Since many investigations have done so far yet, the technical difficulties and high cost in combination with conventional possibilities are needed to be addressed to overcome the issues on the financial side. Hence, microbial oxidation of methane can emerge as a cost-effective candidate to minimize the GHG emission from landfills to the environment. LFG projects are aimed towards generating energy and reduced methane emissions also, embark on bringing positive outcomes for all and sundry. It also creates a partnership among citizens, NGOs, ULB's, government, and industrial partners. However, the LFG projects are significant and have potential benefits in terms of energy, economy, and environment.

Renewability Assessment of a Production System

Sandip Ghosh, JIS College of Engineering, Kalyani, India

Introduction

Mitigation of greenhouse gas emission is one of the most critical responses to climate change, as it plays a central role in implementing the Carbon and Climate Commitments. The direct reductions of on-spot emissions are often a tangible and highly successful demonstration of sustainability policy. The key ingredients lie inherently in all possible production systems active on this planet. Setting a bold aspiration to carbon neutrality often drives deeper cuts in emissions beyond what would be achieved with the simple desires of wise resource usage and cost saving. Higher education is one of society's driving forces of innovation and new ideas. It is in this spirit of discovery and learning that one can start to address the challenge of carbon neutrality. Carbon neutrality is defined as having no net greenhouse gas (GHG) emissions, to be achieved by minimizing GHG emissions as much as possible, and using carbon offsets or other measures to mitigate the remaining emissions. This is an exciting time to undertake a path to a low-carbon future. Each year new technologies and applications appear in the point of becoming economical for wide-scale implementation. The majority of such technologies require achieving carbon neutrality on a national scale. To help focus planning and determine a starting point for carbon mitigation efforts, it is often useful to follow a carbon management hierarchy. A carbon management hierarchy generally outlines broad categories of mitigation strategies like avoiding or reducing emissions through Efficiency and Conservation, eliminating emissions through switching to Renewable (zero carbon) sources of energy and offsetting any remaining emissions. Efficiency and Conservation are often low-cost or cost-saving endeavors and so can be placed as the first-choice solutions. Efficiency generally involves technological improvements to equipment and infrastructure of a production system. The advantage of boosting efficiency typically lies in a very high return on investment and does not require major changes in the behavior of a local community. The drawback is that it typically requires a certain expenditure of up-front capital against the cost savings over the lifetime of the production system. A Green Revolving Fund (GRF), described in financing, is a great method for overcoming this challenge. Another perspective of mitigating carbon footprint is the culture of conservation which typically may not include major capital investments. According to the Intergovernmental Panel on Climate Change (IPCC), in order to limit the global mean temperature increase over 2–2.4°C, global emissions need to be reduced 50%–85% below 2000 levels by 2050. Keeping this broader context in mind, emission reductions must be initiated as soon as possible in order to slow down the adverse effects of greenhouse gases including carbon dioxide and chlorofluorocarbons. Shifting to low-carbon sources of energy typically requires significant advance planning particularly when involving changes to a production system infrastructure. Therefore a detailed analysis of the production system is highly essential to set the optimum strategy of renewability approach.

In the present era an awareness of renewable energy is a common aspect irrespective of branch or streams of engineering and science. A source of energy can be called renewable if natural processes are constantly replenishing it. For example, sunrays, wind, wave energy, geothermal heat and wood are considered renewable resources. Even fossil fuels can be renewable over many millions of years, as geological processes are continually generating new petroleum. But the process is not fast enough to refill oil fields as they are drawn down. For the aforementioned reasons, the term renewability is rather defined on the basis of continued human relationship with a given energy resource i.e., the rate at which humans exploit it compared to the rate at which nature renews again. If the resource is regenerated at a higher rate than it is used, it is considered renewable, but if it is exploited at a higher rate than it is regenerated, it is considered nonrenewable. The more renewable an energy resource is (that is, the faster it can be regenerated at the level it is being used), the less of an environmental impact it has. Wind electricity, has high renewability, as there is essentially no time lag between its use and regeneration. Forest exploitation at rates low enough to permit renewal should be expected to have less environmental impact than exploitation above renewal rates. It is therefore a matter of concern to examine energy technologies having intermittent renewability that can be realistically increased. While an efficient use of a resource can increase renewability, an innovation in the process of turning a non-resource renewable material into a useful resource can be more proficient. Literatures suggest that several presently available energy systems having low renewability may become more renewable in the future (Manzini and Martinez, 1999).

Renewability is a key parameter for evaluating energy technologies according to their environmental impact. Consequently Renewability assessment is of great importance for sustainable development of systems and processes concerned with human welfare. On one hand it deals with calculations of input/output ratio for a specific renewable resource based on benefit analysis. The same is applicable to the systems like wind energy generation farms and wastewater treatment plants (Malca and Freire, 2006). On the other hand such assessments aim to investigate the sustainability of a concerned system by identifying the renewable resource components from its total historical resources use. The second role has a much larger domain of importance in the perspective of mitigating carbon footprints. For various kinds of production systems it can be carried out to find the specific renewability index for each final product (Shao and Chen, 2016a,b). For all products a tag of renewability can be attached so as to distinguish them qualitatively in the perspective of sustainable development. Most of such assessments rely upon thermodynamic accounting methods based on exergy. However, emergy analysis developed by Odum (1996), has been a historical breakthrough regarding the renewability assessment of a wide variety of production systems. Initially it emerged from the analysis of historical resource uses of various systems (Vassallo *et al.*, 2009). Within many of the quality indicators proposed in the literature, the renewability index (RI) is mostly significant due to its concern with original use of renewable resources. In most cases, only a part

of the natural renewable resources are directly utilized by the concerned system. Likely sunlight and rain, are generally identified as renewable resources. But various purchased products are encompassed within nonrenewable resource category, the historical use of renewable resources for the product are often ignored. Almost all the economic products and social services, both renewable and nonrenewable resources have been consumed during their productions. To assess the overall renewability of a production system aided by various kinds of social products, the renewable resources use of each product or service input should be analyzed.

A Review of Renewability Assessments

The renewability assessment of continually replenishing energy sources like the solar energy, wind power and biofuels have been intensively carried out in many literatures. Most of these studies were based on embodied energy analysis where the historical energy use of an energy system has been traced and accounted by net energy analysis or thermodynamic methods, such as energy analysis and exergy analysis. The renewability has been judged by either the input/output ratio of a specific renewable energy source or the proportion of renewable energy use to total energy use (Chen *et al.*, 2011). Solar energy is conventionally believed to be the primary driving force of the ecosphere. Based on these facts energy analysis was first proposed by famous ecologist Odum to quantify the direct and indirect work previously done to make a product or service (Odum, 1988). It conceptualized the 'solar energy' analysis to evaluate the solar energy required directly and indirectly to make a product or service. This approach translates each environmental and economic input, including energy, materials, labor and currency, into solar energy equivalents by utilizing a conversion factor called transformity. Therefore it illustrates the total previous resource use of each product. Till now, the energy analysis has been widely employed to evaluate resources used by various production systems at different times and regional scales (Ulgiate *et al.*, 1995). To illustrate the sustainability, environmental cost and benefit for a particular production system, lot of indicators have been contributed by energy analysis. Like many other exergy based studies, the Renewable Index (RI) is one of the important indicators which express the proportion of total renewable resources. Later such indicators were improved to include the renewable resource consumption triggered by the economic products inputs like those embedded in social products (Yang *et al.*, 2013). In order to assess the overall renewability of a production system, the use of renewable and nonrenewable resource as well as their components of each social product input should be properly identified. Actually, apart from a few essentially natural resources, each material, especially social product or service has consumed both renewable and nonrenewable resources through its supply chain, which cannot simply be classified as total renewable or nonrenewable source. A modified framework proposed by Chen *et al.* (2009) involves an improved indicator for renewability assessment of a production system.

Freshwater is often considered as renewable resources but it was not in the limelight for a long time because of the common perception of considering fossil energy as the only nonrenewable resource in human civilization. The availability of water resources is limited against a specific eco-geographical and socio-economic background. Although there is a wide range of renewable water resource points which don't appear with same production rates. While for the river water it's roughly two to three weeks, for groundwater aquifers it may take several hundred or even thousands of years (Li, 2009). Moreover, the extraction rate is larger in comparison to the underground accumulation and availability of river water throughout the world. Therefore it becomes necessary to account such varying resource points where a lot of extraction has already been done. The term "fossil water" is developed to refer the water from such ground aquifers since their accumulation time is measured at a human time scale (Oki and Kanae, 2006). From the economic perspective it needs a great deal of cost to make the water resources available for end use. Not only the cost of extraction from natural environment, but also the costs involved in treating them before and after use are important in assuring a safe and hygienic environment for the human society. The sustainability characteristics of wastewater treatment have been analyzed from economic, environmental and social perspective in many literatures (Muga and Mihelcic, 2008).

Various methods, for instance, life cycle analysis, energy analysis, exergy analysis, and some integrated approaches (Hellström *et al.*, 2000) have been applied to assess various sustainability indexes in relation with carbon footprints. The demand of water would continue to increase along with the fast growing population and ever growing living standard. Therefore the renewability assessment of water related system is highly crucial in the perspective of its efficiency and policy making. Transformity, defined as the energy required for making a unit of product or service, has been calculated by a plenty of scholars (Odum *et al.*, 2000). The transformity data for environment inputs such as sunlight and wind power are relatively constant where Odum's database (Odum *et al.*, 1988) is applicable. For the social products and services, energy was estimated by multiplying the monetary cost by a single energy to money ratio (Ukidwe and Bakshi, 2004). Process analysis tries to analyze each individual stage to trace the historical energy of the concerned product. But it deals with truncation error and data inconsistency jeopardizing the reliability of energy studies. In contrast with process analysis, the input-output analysis is a top-down approach (Leontief, 1970). By integrating the consistent statistics with various ecological impacts, the input-output analysis can efficiently provide up-to-date data for ecological accounting studies. It has been successfully applied to study the environmental implications of natural resources use and environmental emissions like energy, carbon, pollutant etc., within an economy (Zhou, 2008).

Methods of Renewability Assessments

Evaluation of Exergy Based Renewability Index

The search for thermodynamic quality standards is one of the most interesting challenges of the Engineering Thermodynamics. In the last decades, this concern is no more restricted to the performance quantification of a given process or equipment, but it

extends to all the boundaries of any energy conversion process, including its energy inputs and wastes. For every process, equipment and a given output, two major drawbacks can be identified

- A larger energy input utilization as smaller is the conversion efficiency,
- A larger quantity of wastes and consequently a higher potential to generate environmental impacts, as smaller is the conversion efficiency.

The concept of exergy was originated from the formulation presented by Gouy (1889) and Stodola (1898), which shows that the maximum potential for a system to perform work is a function of its internal energy and the ambient conditions. For a prolonged period of time the concept of renewability has been associated to mass and energy balances, not taking into account the reduction of the quality of the energy i.e., exergy destruction related to energy conversion processes. The traditional definition of sustainability, that calls for policies and strategies that meet society's present needs without compromising the ability of future generations to meet their own needs, Odum (1996) does not provide a rational way to quantify this ability. Exergy originating from the contrast between sun and space drives flows of energy and matter on the surface of Earth. This exergy input is destroyed in order to keep the natural cycles responsible for recycling materials on earth, and a small part is stored as fossil fuels and mineral ores. Recycling again takes time and exergy to be accomplished, but total recycling is not possible due to the second Law of Thermodynamics. Therefore the Origin of its energy source and Efficiency of the energy conversion processes should be taken into account whenever discussing renewability of any product (De Oliveira, 2012). Based on these facts a renewability exergy index can be defined which accounts the exergy associated to the useful products of a given energy conversion process or a set of processes, the destroyed exergy, the exergy associated to the fossil fuels required, the needed exergy to deactivate the wastes, and the exergy of by-products and not treated wastes.

Exergy flow rate $\dot{B}$ can be calculated by the following general equation in which four components are considered: kinetic exergy (k), potential exergy (p), physical exergy (ph), and chemical exergy (ch).

$$\dot{B} = \dot{B}_k + \dot{B}_p + \dot{B}_{ph} + \dot{B}_{ch} \quad (1)$$

Where, specific physical exergy is

$$\dot{B}_{ph} = (h-h_0) - T_0(s-s_0) \quad (2)$$

Here h is the specific enthalpy, s is the specific entropy and the subscript 0 is referred to the dead state. The exergy balance for a control volume (CV) operating in steady state express the destroyed exergy

$$B_{destroyed} = \sum_{in} \dot{B}_i - \sum_{out} \dot{B}_i + \sum \dot{B}^Q - \dot{W} \quad (3)$$

Where, $\sum_{in} \dot{B}_i$ and $\sum_{out} \dot{B}_i$ are the sum of inlet and outlet exergy flow rates respectively. $\sum \dot{B}^Q$ is the sum of thermal exergies, and $\dot{W}$ is the power in the CV.

Exergy efficiency η_B measures the ratio between the exergy outflow rate and the exergy inlet rate. Exergy product consists in the difference between the exergy content of the separated products $\dot{B}_p$ and that of the mixture $\dot{B}_M$. The exergy inlet rate is given by the exergy flow rate $\dot{B}_U$ used to provide the exergy flow rate output. The utilized exergy $\dot{B}_U$ is the exergy content of the fuel used to satisfy the requirements of the processes

$$\eta_B = \frac{\sum \dot{B}_p - \sum \dot{B}_M}{\dot{B}_U} \quad (4)$$

The renewability exergy index λ measures the ratio between the exergy associated with the useful product of the process and the sum of the exergy associated to the fossil fuels required, the destroyed exergy, the needed exergy to deactivate the wastes, the exergy related to waste disposal and the exergy of wastes that are not treated or deactivated (Sánchez and De Oliveira, 2015)

$$\lambda = \frac{\sum B_{product}}{B_{fossil} + B_{destroyed} + B_{deactivation} + B_{disposal} + B_{emission}} \quad (5)$$

Where,

- $B_{product}$ represents the net exergy associated to the products and by-products.
- B_{fossil} is the non-renewable exergy consumed on production processes chain.
- $B_{destroyed}$ is the exergy destroyed inside the system, punishing the process for its inefficiencies.
- $B_{deactivation}$ is the deactivation exergy for treating wastes, when they are carried to equilibrium conditions with the environment.
- $B_{disposal}$ is exergy rate or flow rate related to waste disposal of the process.
- $B_{emission}$ is the exergy of wastes that are not treated or deactivated.

Depending on the value of the renewability exergy index (De Oliveira, 2012), it indicates that

- Processes with $0 \leq \lambda \leq 1$ are environmentally unfavorable.
- For internal and externally reversible processes with non-renewable inputs, $\lambda = 1$.
- If $\lambda > 1$ the process is environmentally favorable, and additionally, increasing implies that the process is more environmentally friendly.
- When $\lambda \rightarrow \infty$ it means that the process is reversible with renewable inputs and no wastes are generated.

Energy Return on Investment (EROI) Method

In physical assessment of renewable and sustainable energy technologies for mitigating greenhouse gasses and overall carbon footprint, system indicators play an essential role during the evaluation (Chen *et al.*, 2011). Although theoretically a totally renewable energy should not involve any fossil energy requirement, in a practical scenario it requires both renewable and nonrenewable energy inputs. In this regard a remarkable breakthrough is the basic concept of energy return on investment (EROI). It is defined as the ratio of energy extracted or delivered by a process to the energy used directly and indirectly in that process (Cleveland, 2007).

EROI is calculated from the following equation, although the details are really involved:

$$\text{EROI} = \frac{\text{Energy returned to society}}{\text{Energy required to get the energy}} \quad (6)$$

The numerator and denominator are necessarily assessed in the same units so that the ratio derived is dimensionless. This example means that a particular process yields 30 joules per investment of 1 J. EROI is usually applied where the energy resource leaves a production facility like the mine-mouth, wellhead or a farm gate. So it can be denoted more explicitly as EROI_{mm} . In another approach EROI is the standardized energy output divided by the summation of direct energy used at production site and indirect energy used to manufacture the machinery and products used, consumed to generate that output. This results in a measurement of standard EROI i.e., EROI_{st} . The numerator of the EROI equation is the product of the quantity of energy produced and the energy content per unit. Determining the energy content of the denominator is usually difficult. The energy used on site may be manifold like the energy used to rotate the drilling bit when drilling for oil, the energy used to excavate when mining for coal, or the energy used to operate the farm tractor when harvesting corn for ethanol. The energy involved in the manufacturing of concerned equipments is also under the purview (Hall, 2011). EROI values for our most important fuels, liquid and gaseous petroleum, tend to be relatively high. World oil and gas has a mean EROI of about 20:1 (Lambert *et al.*, 2012). Analysis of EROI values for nuclear energy suggests a mean EROI of about 14:1. Hydroelectric power generation systems have the highest mean EROI value, 84:1. Nearly all renewable energy systems appear to have relatively low EROI values when compared with conventional fossil fuels. A question remains as to the degree to which total energy costs can be reduced in the future, but as it stands most “renewable” energy systems appear to be still heavily supported by fossil fuels. They are considerably more efficient at turning fossil fuels into electricity than are thermal power plants, although it takes many years to get all the energy back (Fig. 1).

The reciprocal of EROI has been addressed as energy cost indicator to denote how many energy times of cost used in the whole manufacturing process over the energy are contained in the final product. Fossil energy ratio, defined as the ratio between the biofuel energy content and the fossil energy input, has been used to identify whether a biomass derived fuel is renewable (Chen and Chen, 2011). Few literatures has reported flaws about EROI, such as varying answers to the same question, controversial boundaries of the analysis and dependence upon monetary data. Despite these limitations, EROI is still a basic concept to indicate renewability when considering energy policy and the future prospects for modern civilization.

Net Energy Analysis

During the worldwide energy crisis in 1970s, the net energy analysis was first proposed to assess the energy exploitation efficiency of a conventional energy supply system (Berthiaume *et al.*, 2001). To assess the renewability of a sample production unit having possible carbon footprints, an indicator called NEIED (nonrenewable energy investment in energy delivered) was proposed (Cleveland, 2007). At early stages only fossil energy was concerned to deal with conventional energy system. Subsequent studies made some progresses by additionally concerning the specific renewable energy sources. However its historic consumption embodied in the production of the material inputs was not assessed in many cases. For example, in a sustainability assessment of a 1.5 MW solar power tower plant in China (Wall and Gong, 2001), while accounting a nonrenewable energy cost only the fossil energy cost of the material inputs were accounted. However with the previous solar energy cost for the geophysical formation of the fossil fuel was not mentioned. A lot of existing renewability assessment studies has used thermodynamic analysis to trace and

Fig. 1 Mean EROI with standard error values of power production systems. Reproduced from Hall, C.A.S., 2011. Introduction to special issue on new studies in EROI (energy return on investment). Sustainability 3 (10), 1773–1777.

measure the embodied energy of a production system especially while considering the energy inside soil and water. Therefore, the term 'nonrenewable energy investment in energy delivered' (NEIED) is expressed as

$$\text{NEIED} = \frac{\text{NE}}{E_{\text{OUT}}} \quad (7)$$

Where, NE is the nonrenewable energy used directly and indirectly in the production process, and E_{out} is the net output energy. NE can be calculated as,

$$\text{NE} = \sum \text{NE}_i = \sum \text{Input}_i \times C_i \quad (8)$$

Where, NE_i denotes the nonrenewable energy used directly and indirectly in the production of the i th input, Input_i to the whole chain of a production farm. C_i is defined as the nonrenewable energy-intensity coefficient which indexes the proportion of direct or indirect nonrenewable energy demand for the production process. Such coefficients can be measured by one of two general methods: namely process analysis or input–output (I–O) analysis. Both methods require the same data and would yield the same result in most cases. The more nonrenewable energy required to produce an output, the less we can say that this output is renewable. Significant cases could be identified for different ranges of NEIED values. $\text{NEIED} < 1$ is for a renewable process in which more energy is produced than NE invested, while $\text{NEIED} > 1$ is for a nonrenewable process in which more NE is consumed than energy produced (Yang and Chen, 2012). Smaller the NEIED, higher is the renewability of the production system. Similarly, the Greenhouse Gas (GHG) emissions associated with NE cost can be calculated as

$$\text{GHG} = \sum \text{GHG}_i = \sum (\text{INPUT}_i \times G_i) \quad (9)$$

Where, GHG_i denotes the direct and indirect Greenhouse Gas emissions in the production of i th inputs, G_i is defined as the GHG-intensity coefficient of the i th input (Zhou, 2008). Lesser GHG emission of a production system is indicative of higher renewability.

Emergy Analysis

Emergy is the availability of energy or exergy that is used up in transformations directly and indirectly to make a product or service. The unit of emergy is the emjoule. For example, sunlight, fuel, electricity, and human service can be put on a common basis by expressing them all in the emjoules of solar energy that is required to produce each (Brown and Ulgiati, 2004). Solar emergy is expressed in solar emjoules or sej. The more work that is done to produce something, the more energy must be transformed to perform that work, and higher the emergy value stored in the product. Emergy is therefore a global measure of the sum of the energy flows in the processes required to produce something. Few basic block diagrams describe emergy systems. Relevant symbols used in the energy systems diagram have been depicted in Fig. 2.

Fig. 3 illustrates the pathways (flows) and conservation of energy within a typical production system. The key aspects include flows of energy into and out of the system, transformation of energy and its storage in various pools within the system, consumption of energy by a process to do work, and flows of energy between storage pools.

Exergy represents the real proportion of the energy that is available to perform mechanical work:

$$E_x = (\text{Gibbs free energy}) + (\text{Gravitational energy}) + (\text{kinetic energy}) \quad (10)$$

Brown and Ulgiati (2002) defined the solar emergy (E_m) of the flow from a given process as the solar energy that is directly or indirectly required to drive the process. The unit of solar emergy is the solar emjoule (sej):

$$E_m = \sum E_i \text{Tr}_i \quad (11)$$

Where, E_i is the available energy (free energy) content of the i th independent input flow into the process and Tr_i is the solar transformity of the i th input flow. Transformity is the emergy of one type required to create a unit of energy of another type. An important concept in emergy analysis is the solar transformity, which represents the solar emergy (in solar emjoules, sej) required to provide 1 J of a service or product (Odum, 1996). Solar transformity is therefore measured in sej J^{-1} . For example, 159,000 J of solar energy can be transformed into a quantity of wood through photosynthesis, with some loss during transformation processes. If that wood can release 1 J of energy by combustion, the transformity of the wood will be 159,000 sej J^{-1} (Fig. 4). Transformity captures the emergy invested per unit of product or useful output (Brown and Ulgiati, 2004). Transformity (Tr) can therefore be specified as the ratio of used up input emergy or available energy to the output exergy as follows,

$$\text{Tr} = \frac{E_m}{E_x} \quad (12)$$

Fig. 5 is a generic example of the emergy diagram which describes the interactions between the different stages of a system involved in the production of a product whether a good or service. Independent Sources represented by circles can be three types: (local) renewable resources R, (local) non-renewable resources N, and flows passing through the economic system S (Wilfart and Corson, 2012) synthesized the sources as shown in Table 1. Varying interpretations may exist when classifying a resource, for example "nonrenewable" or "service". Although it depends on the given modeler's choice, the choices made in the analysis should be explicit. Emergy analysis is governed by a set of rules which connects them. The (total) emergy of co-products is equal to the input emergy E_{mi} and the total input emergy within a junction is distributed in proportion to energy outputs. Two systems with the same production process may have different transformities like $\text{TR1} < \text{TR2}$. If the second system uses more renewable resources

Fig. 5 Example of an emergy diagram of a production system.

Table 1 Classification of sources for emergy evaluation

Description		Unit UEV	Notation
Environmental contribution (local)			
Renewable resource	Sun, tidal, wind and other natural sources	seJ/J	R
Non-renewable resources	Fossil fuel, minerals and other fuels	seJ/unit	NR
Interaction with the economic system (external)			
Equipment (good)	Machine	seJ/\$	S
Service	Electricity, employees labor	seJ/\$	S
Input emergy which is modified to outputs = $R+NR+S$			

Table 2 Emergy ratios used as different renewability index

Emergy ratio	Formulation	Implication
Emergy Yield Ratio (EYR)	$EYR = \frac{Em_p}{Em_s}$	The larger the EYR or Production ratio, the lower the service contribution
Emergy Loading Ratio (ELR)	$ELR = \frac{Em_r + Em_n}{Em_r}$	Smaller ELR indicate more significant emergy portion of local renewable resources. An increased value demonstrates a production system mainly using non-renewable resources
Emergy Investment ratio (EIR)	$EIR = \frac{Em_s}{Em_r + Em_n}$	Lower EIR shows more tendency of a product obtained from local resources (renewable or non-renewable) and consequently more emergy cost or investment flow through the economic system
The Emergy Sustainability Index (ESI) is defined as:	$ESI = \frac{EYR}{ELR}$	An increased ESI value corresponds to a production system which uses local renewable resources and is therefore considered to be sustainable
The recycling fraction %R	$\%R = \frac{Em_r + Em_{sr}}{Em_p}$	This fraction takes account of the share of local renewable emergy, but also connects the renewable part coming from the economic system

for its production, then even if its transformity is higher than that of the first system, the second system should be retained. In extension with transformity evaluation, another important parameter of interest is the unit emergy value (UEV) which is expressed as the emergy value for a product unit in seJ/g. Fossil resources (coal, natural gas and oil) from different geological eras can also be analyzed to judge their renewability. Minerals are assessed from a so-called (natural) enrichment factor. For interactions between the studied system and the economic environment, the emergy value of a given currency is also needed (Lei *et al.*, 2014).

The first step of emergy analysis is gathering all inputs which cross the boundaries of a given system as shown in Fig. 5. This information is generally presented in the form of a table. Each constituent is referred to an identifier with an associated unit, the quantity of the constituent used and the unit emergy content. The last column calculates the total emergy of the constituent. Local resources can be separated as renewable or non-renewable which are imported or transported within the market based system. To compare renewability of two production systems concerned to the same output product, five major emergy ratios are defined in Table 2. For example in the production of Aluminum, it is first extracted from a mine, then refined and finally converted into an ingot (Olivier, 2016). For simplification, let's assume that electricity is the only given source of energy during the production process. The emergy diagram

associated with this process is given in Fig. 5. For a case study of production, Buranakarn (1998) indicated that a quantity of $4.17\text{E}+5$ tons of minerals were used. From a database, he obtained the unit energy content ($1.17\text{E}+10$ seJ/g) as well as the total energy. Through similar analysis for electricity and human labor, he calculated the total quantity of emergy. Table 3 summarizes the above approach exploiting the annual production of aluminum ingots in USA and the unit energy content of this product.

Modified Emergy Analysis Based on Input-Output Analysis

As discussed earlier, emergy analysis translates all goods, services, environmental inputs like sunlight, wind, rain and tides, into a common unit of available energy. However for social products, transformity database is dependent upon time-consuming process analysis which traces the historical emergy of a concerned product at each stage of the production system. Leontief (1970) introduced the input–output analysis based on economic statistics. It organizes matrices of all the intermediate inputs into goods and services by integrating the consistent statistics with various ecological impacts. The input–output analysis can efficiently avoid the truncation errors of process analysis and provide unified data for renewability studies. It has been successfully in the assessment of environmental implications regarding natural resources use and environmental emissions. The modified diagram for the emergy based renewability assessment of a production system is shown in Fig. 6, following the methods developed by Odum (1988). Natural resources accounted by emergy can be classified into renewable resources (RR) such as sunlight, wind power etc., and nonrenewable resources (NR) such as soil, fuels, and minerals. Besides directly utilizing natural resources from the environment (L), a production system also indirectly utilizes resources by purchasing products and services from the economy (P). Since the human society consumes both renewable and nonrenewable resources in its evolution, each product and service consists of both renewable (RP) and nonrenewable (NP) components. Following steps demonstrate the resource accounting procedure as the basis of renewability assessment of a production system (Shao and Chen, 2016a).

- (1) Itemize all the inputs of the concerned system, including both environmental inputs as local sources and social products and services as purchased sources to form an inputs inventory of the concerned system. The quantity of environmental inputs (QE) should be in Joule and transformity in seJ/J. The quantity of purchased input (QP) is in monetary unit.
- (2) Determine the transformities of all inputs of the concerned system. For environmental inputs transformity (TE) are relatively constant as per data contributed by Odum (1996). To trace the previous resources consumption of a social product, the transformity database should cover both renewable and nonrenewable transformity data of each product or service input to

Table 3 Emergy table for annual production of USA aluminum

Sl. no.	Element	Unit/year	Quantity	UEV (seJ/unit)	Emergy (seJ/year)
1	Aluminum mineral	g	$4.17\text{E}+11$	$1.17\text{E}+10$	$4.88\text{E}+21$
2	Electricity	J	$1.08\text{E}+15$	$1.74\text{E}+05$	$1.88\text{E}+20$
3	Labor	\$	$2.09\text{E}+07$	$1.15\text{E}+12$	$2.40\text{E}+19$
Annual quantity		g	$4.00\text{E}+11$	$1.27\text{E}+10$	$5.08\text{E}+21$

Fig. 6 Diagram for emergy analysis of a production system. Reproduced from Shao, L., Chen, G.Q., 2016b. Renewability assessment of a production system: Based on embodied energy as emergy. *Renewable and Sustainable Energy Reviews* 57, 380–392.

make subsequent renewability assessment possible. After preparing the database the corresponding transformity for each product or service input (TP) is calculated from corresponding economy input–output table.

- (3) The energy as energy embodied in the supply chain of each input can be calculated by multiplying the transformity by its quantity. By adding up the energy of both environmental and social product inputs, the total resource use of the concerned system is given as:

$$U = \sum_{i=1}^n TE_i \times QE_i + \sum_{i=1}^n TP_i \times QP_i \quad (13)$$

According to the energy theory, the related energy flows of a production system and the indicators used for assessing the renewability, efficiency and performance are respectively described in Table 4. The previous energy studies used to consider a product or service as completely renewable or completely nonrenewable. As for the natural resources that can be true. But for products or services, this perception is inappropriate (Shao and Chen, 2016a). The production of a product or service needs both renewable and nonrenewable resources in its making which makes the estimation more complicated. In general cases with heavy economic investment, the input–output analysis is necessary for energy analysis especial the renewability assessment studies considering that it realizes the complete modeling of the whole economy as organizing matrices of all intermediate inputs.

Case Studies

Renewability Assessment for Biofuel Production

Biofuel is one of promising option to reduce carbon footprints and reducing greenhouse gas emission. This study presents an efficiency and renewability analysis of the production of three biofuels: rapeseed methyl ester (RME), soybean methyl ester (SME) and corn based ethanol (EtOH). The overall production chain to transform the crops into biofuels, including the crop production, industrial conversion into biofuels, production of agricultural resources like pesticides, fertilizers, fuel, seeding material and industrial resources like energy and chemicals were taken into consideration. Simultaneously, byproducts of the agricultural and industrial processes have been taken into account when resources have to be allocated to the biofuels.

Three production chains were quantified in exergy terms. The reference state considered was temperature at 298K and pressure at 1 atm with composition as per standard literature (Szargut *et al.*, 1988). In Fig. 7, the overall production chains of RME, SME, and EtOH are represented where allocation of renewable and nonrenewable resources to the delivered biofuels and byproducts are done on exergy basis. The thermodynamic second law analysis revealed that corn-based EtOH results in the highest production

Table 4 Energy indicators of renewability assessment of a production system

Item	Symbol and algorithm	Item	Symbol and algorithm
Local Energy	$L = RR + NR$	Environmental Loading Ratio (stress on the environment)	$ELR = (NR + NP) / (RR + RP)$
Local Renewable / Nonrenewable Energy	RR / NR	Energy Yield Ratio (for purchased resources)	$EYR = U / P$
Purchased Energy	$P = RP + NP$	Locality Index (for environmental contribution)	$LI = L / U$
Purchased Renewable / Nonrenewable Energy	RP / NP	Environmental Sustainability Index (ecological sustainability)	$ESI = EYR / ELR$
Total Resources Use	$U = L + P$	Renewability Index (percent renewability)	$RI = (RR + RP)$

Fig. 7 Exergy flow for annual production of biofuels on 1 ha ($\text{GJ ha}^{-1} \text{yr}^{-1}$), including byproducts. Percentages show the shares in the output of respective process on exergy basis (a) RME, (b) SME, (c) EtOH. DDGS- Distiller's dried grain. Reproduced from Dewulf, J., Vanlangenhove, H., Vandeveld, B., 2005. Exergy-based efficiency and renewability assessment of biofuel production. *Environ. Sci. Technol.* 39, 3878–3882.

rate with an exergetic fuel content of $68.8 \text{ GJ ha}^{-1} \text{ yr}^{-1}$, whereas the RME and SME results were limited to 47.5 and $16.4 \text{ GJ ha}^{-1} \text{ yr}^{-1}$. The allocated nonrenewable resource inputs are 16.5, 15.4 and $5.6 \text{ MJ ha}^{-1} \text{ yr}^{-1}$ respectively. This means that these biofuels, generally considered as renewable resources, embed a nonrenewable fraction of one-quarter for EtOH and even one-third for RME and SME. The renewability can also be judged in terms of exergy breeding. The energy or exergy breeding factor (BF_{ex}) and the net energy or exergy value (NEnV or NExV) assesses how much renewable resources are bred from nonrenewable resources. It turns out from the detailed analysis that not only for the overall production chain, corn-based ethanol proves to be the most suitable biofuel in terms of efficiency and renewability (Dewulf *et al.*, 2005). The analysis reveals an overall industrial metabolism exergy breeding factor i.e., overall BF_{ex} of 4.1 for EtOH based production with lowest nonrenewable fraction of 24.3%. RME and SME show overall BF_{ex} values close to 3 and a nonrenewable fraction of about one-third.

Renewability of Various Power Production Systems

Renewability of power production systems can be analyzed by many of the methods outlined earlier. The first step is to devise the Emergy diagram through detailed analysis of the system. Input data for each item in the evaluation tables are the operational data of each plant and are converted into appropriate units by suitable conversion coefficients. Unit oil equivalents (goil/unit) are used for energy evaluation and transformities (sej/unit) for emergy evaluation, to yield net energy and emergy values for each input item. Energy values are initially expressed as grams of oil equivalent followed by grams of released carbon dioxide, by means of an average oil-to-carbon dioxide conversion coefficient. Energy, emergy, and CO₂ flows are then summed, yielding a total that is divided by the amount of the product of each plant to calculate its energy cost, its transformity, and its associated carbon emissions. This evaluation offers an opportunity to evaluate the effects of greenhouse gas emissions in the concerned process. Finally to get an overall picture of plant performance, energy, emergy and carbon-flow related indicators are assessed. All inputs and outputs of the production systems are expressed on a yearly basis. Fixed capital equipment, machinery, buildings, and so on are divided by their estimated useful life (10–30 years). CO₂ production is calculated for direct fuel combustion in thermal plants using multipliers of indirect energy consumption for their production. These multipliers are derived from a standardized comparison of literature in this field (Brown and Ulgiati, 2004).

The case study is based on data provided by Italian National Electric Company (ENEL) on the average performance of Piombino 1280 MWe power plant situated at Tuscany, Italy. The plant consists of four 320 MWe boiler-turbine-generator groups, cooled by the seawater from nearby Mediterranean Sea. A conventional oil fuelled thermal power plant consists of a fuel inventory, boilers with pumps for steam generation, steam turbines, electric generators, set of transformers for easier transport to end users, chimneys for the release of combustion gases to atmosphere, and finally a set of heat exchangers to condense the steam by means of sea water (approx $44 \text{ m}^3/\text{s}$). Fuel desulfurization devices along with antipollution filters and scrubbers at the chimney mouth are also considered. As per the material components all inputs were sorted and suitable transformity were chosen from available literature. Labor and services are also accounted. Waste heat and chemicals released to the environment are quantified. The amount of environmental services (cooling water, wind, etc.) needed for dispersal, dilution and abatement is calculated through emergy accounting procedure. Fig. 8 shows the direct and indirect annual environmental flows to run the plant structure (assuming a lifetime of 25 years). The assessment automatically reflects the GHG emissions and its routes in the production system.

Fig. 8 System diagram of a thermal power plant and its environment demonstrating the use of environment and nonrenewable energy sources. Reproduced from Brown, M.T., Ulgiati, S., 2004. Emergy analysis and environmental accounting, Encyclopedia of Energy 2, Elsevier Inc.

Another investigation consists of a 2.5 MW wind powered field, composed with 10 single-blade, 250 kW, wind turbines M30-A, sited in southern Italy. The wind field was installed in the year 1995 by the Riva Calzoni Company. The distance between two generators is 150 m. Each turbine is located on the top of a 33 m support tower. Operating wind speeds are between 4 and 25 m/s. The turbine automatically stops in off design conditions. This remote controlled wind field does not require any local labor for its daily activity. The energy systems diagram of this case is elaborated in Fig. 9. Net Energy analysis (NEA) or Embodied Energy Analysis (EEA) typically evaluates energy sources and the process outputs in their heat equivalents. In this regard EROI is considered as a measure of the first law energy efficiency of a production unit. The total input energy in this case is derived by multiplying all goods and materials consumed in the construction per year of the average life span added with the annual maintenance of plants by energy equivalent multipliers and the annual energy consumed directly and indirectly. The output as electricity is converted to joules using the standard conversion of 3.6×10^6 J/kWh. Table 5 shows the energy accounting for the wind turbine case. Each item related to the investigated case study is multiplied by an appropriate transformity to get the emergy input. The total emergy is a measure of the total environmental support or ecological footprint to the process (Bargigli and Ulgiati, 2003). Finally, a new transformity for the process output is calculated by dividing the total emergy by the exergy of the product. Further renewability indicators like emergy yield ratio, environmental loading ratio, emergy density and renewability or emergy

index of sustainability are calculated. A relative comparison on the two aforementioned case studies has been depicted in Fig. 10 where all type of renewability indicators has been assessed.

Table 5 shows that wind emergy accounts for about 82% of the total emergy input, while labor and services (4%) and goods and machinery (14%) play a much smaller role. Emergy analysis demonstrates the whole process by considering hidden environmental flows and evaluating their role by means of a common measure of environmental quality. Allied literature shows that the EROI of a hydel plant is quite high in the range of 7.67 in comparison to the oil fired power plant with 0.30. A production system having lower environmental loading ratio also indicates higher energy density along with higher renewability index. A series of emergy performance indicators show that the main contributions to any electricity generation process are the driving forces of fuels or renewable sources, followed by the emergy associated with plant components. The other emergy indicators support this point by showing low Emergy Yield Ratios for oil-powered plants. High ELRs characterize oil-based patterns, as well as bioethanol electricity, while very low ELRs shown by the processes signify a larger degree on renewable. As a consequence, the aggregated sustainability measure expressed by the EIS ranges from a low 0.06 for oil based processes up to a significantly high 25 for wind-based ones.

Conclusion

This article is a brief synopsis of several types of renewability assessments possible for a production system. Starting with the basic exergy based calculations, the evolution of several important indicators have been discussed as per relevance. Methods detailed here, have been applied successfully by many researchers to account the sustainability of various production processes for example harnessing geo-thermal energy or just a simple recycling of wastewater for everyday use. Emergy accounting methodology has been discussed in details to understand versatile energy system diagrams for assessing almost all kind of production systems and affixing a renewability index to every product. Systematic analysis reveals the exergetic efficiency of each element and process used in the whole production unit to identify a resource which might contribute increasing the renewability index. Case studies have been incorporated to clarify the usefulness of emergy concept as well as the application of input output based transformity database. EROI based Case studies have exploited the use of net energy analysis for biofuels production systems through stage-wise process analysis. Ecologically best process was identified to minimize the possible carbon footprints of the production system. Emergy-based case studies of electricity productions system are presented for a better understanding of emergy indicators as well as decision making for prolonged future use. With the renewability approach presented here, a huge number of case studies can be assessed which varies from ecosystems to socioeconomic systems, biosphere, agriculture, industry, tourism, recycling patterns and generation. In all cases, the common aspect is to evaluate all forms of energy inputs, materials and human services directly or indirectly related with carbon footprints which help to measure the past and present environmental support to any production system. The obtained renewability of various products is crucial to promote sustainable economic development as people and firms can prioritize their options with regard to product's renewability label. It is

expected that a perfect scrutiny of production systems in terms of renewability will certainly minimize the overall level of carbon footprints and at the same time will integrate systems leading to least contribution in global warming.

Introduction

The rapid growth of industrialization and simultaneous increase in population all over the world have elevated the air pollution to a very critical level, which threatens public health, deteriorates the environment, and damages property and landscape. The combustion of fossil fuel has led to increase in greenhouse gases (GHGs) and carbon footprint, which has resulted in higher global temperature and climate change. It is expected that the global temperature will rise from 1°C to 6.4°C by 2100 as a consequence of increase in the concentration of GHGs by consumption of fossil fuels in the atmosphere (Pachauri, 2007). Realizing the impact of global warming, almost all countries over the last few decades have introduced increasingly stringent legislation restricting permissible levels of pollutant emission from major combustion systems such as electricity generating power stations, furnaces, and industrial plants as well as from automobiles and aircrafts using fossil fuels. To mitigate greenhouse gases and carbon footprint, it is expected that the use of new and cleaner methods and fuels particularly from renewable energy sources will play a significant role. Amongst different sources of renewable energies, a very promising future energy source is biomass. This is because biomass has distinct advantages over the use of other renewable energies like solar energy and wind power, which are restricted because of their intermittent power generation. While biomass energy is the only renewable energy that can be used in the form of gas, liquid, or solid, it could as well replace the fossil fuel. Besides, if biomass is used as fuel, net carbon emission to the environment is zero because biomass absorbs the same amount of carbon in growing as it releases when consumed as fuel. Also because of very low sulfur content, the emission of sulfur dioxide (SO₂) is low from biomass. Biomass has remained a major source of energy for mankind since the inception of the civilization. Currently biomass accounts for about 10% of the global energy supply, of which two-thirds is used in developing countries for cooking and heating (IEA Task 40, 2003). Although trees and plantations are the main sustainable source of biomass, a number of other sources of biomass also exist. These include but are not limited to agricultural residues, forest residue, animal manure, industrial waste, and municipal/household solid waste. The majority of the biomass materials available in developing countries are used inefficiently in traditional ways, which causes extensive pollution to the environment. Incomplete combustion leads to the formation of extensive smoke. Exposure to smoke from indoor biomass burning is a known major cause of acute respiratory infection and chronic lung disease. However, biomass fuels currently used in traditional energy systems could potentially provide a much more extensive energy service than at present if these are used efficiently. Recently, there is a renewed interest in biomass-based energy because of the following reasons: (1) recent developments relating to the conversion technology and biomass production that made bioenergy competitive with fossil fuel-based energy generation in some situations, (2) environmental benefits provided by the modern biomass energy, (3) increasing concern over energy security and diversity of energy supply, (4) employment generation and rural development, and (5) restoration of degraded lands as a result of plantations and possibility of increase in biodiversity. Since biomass could be used for off-grid power generation, it could provide energy access to all sections of society while addressing the issue of mitigation of GHGs and carbon footprint. Scientists and researchers throughout the world have investigated different methods of converting biomass into useful energy. These methods are broadly classified into three routes: The biochemical conversion route, thermochemical conversion route, and physical conversion route. In the biochemical conversion route, biomass can be converted into either biogas through the anaerobic digestion process or ethanol through fermentation process. In the thermochemical conversion route, there are mainly three processes, namely, pyrolysis, gasification, and combustion. In pyrolysis, biomass is converted into a liquid fuel popularly known as bio-oil. In gasification, biomass is converted into a gaseous fuel known as syngas or producer gas. In combustion, biomass is converted into heat energy in the form of flue gas. On the other hand, in the physical conversion route, biomass is squeezed and oil is extracted that is further processed to use as diesel, and this is known as biodiesel. Different routes of converting biomass into useful energy are shown in Fig. 1.

Different Routes of Converting Biomass into Useful Energy

There are three different routes for converting biomass into useful energy: Biochemical conversion, thermochemical conversion, and physical conversion. Each process has its own advantages and limitations. These processes are described in detail below.

Biochemical Conversion Route

There are two different biochemical process routes for conversion of biomass: Anaerobic digestion and fermentation. These two processes are discussed below.

Fig. 1 Different routes of biomass conversion.

Fig. 2 Schematic diagram of a typical biogas digester.

Anaerobic digestion

Anaerobic digestion is the process by which biomass is converted into biogas and other energy-rich organic compounds through biological process in the absence of oxygen. The diverse microorganisms break down organic material and convert it into other forms through a series of metabolic reactions such as hydrolysis, acidogenesis, acetogenesis, and methanogenesis. Biogas produced from anaerobic digestion of biomass is primarily a mixture of methane and carbon dioxide. It also has small amounts of hydrogen sulfide and moisture. The high amount of methane in biogas allows biogas to be used as a replacement for fossil fuel to generate heat or electricity (Pellera and Gidarakos, 2017). This process has the advantage of low energy requirement for operation compared with other biomass conversion routes. The anaerobic digestion of biomass reduces the environmental pollution because the sealed environment of the process prevents exit of methane into the atmosphere and burning of the methane will release carbon dioxide. The main disadvantages of anaerobic digestion are the long retention times and the low removal efficiencies of organic compounds. Anaerobic digestion of biomass has potential application to reduce the environmental load as compared with conventional sanitary landfills. The design of the reactor has a strong influence on the performance of the digester. Different types of reactor design have been proposed by the researchers in the view of improving the rate of reaction for the treatment of biomass. Fig. 2 shows the schematic of a basic anaerobic digester unit. It has different components as discussed below.

Input slurry tank: Initially the entire feed material would be collected and blended with water in the tank. After blending the ready feed material would be fed in the digester chamber. The feeding is a routine process to be followed up once daily to extract the maximum efficiency from the digester.

Digester chamber: Here the input slurry along with water is fermented and as a result methane and other gases will be produced in the chamber. The gas generated in the chamber will get accumulated at the top in a floating dome. Floating type dome is generally used to give extra storage space without requiring any extra land or incurring any additional cost for the gas storage tank. It also maintains uniform output gas pressure with the help of its metal dome's weight without using any additional compressor or blower.

Fig. 3 Ethanol production from biomass through fermentation.

Output collection chamber: This chamber is used to collect the final output, which is in the form of semiliquid state and is also a by-product of this process. This by-product is enriched organic manure and can be directly used in the agriculture farming.

Anaerobic digestion is a simple process for converting organic waste into energy and simultaneously reduces the environmental pollution. However, it can suffer from process instability, which limits wider application of the process for energy production. Recent studies indicate that process monitoring is the best method of achieving improved process stability and higher conversion efficiency.

Fermentation

Fermentation is a metabolic process in which biomass is converted into ethanol through the action of enzymes. Ethanol can be produced from any biomass feedstock that contains appreciable amounts of sugar or materials that can be converted into sugar such as starch or cellulose. Ethanol is considered as the cleanest liquid fuel alternative to fossil fuels for transportation because it contains 35% oxygen that helps complete combustion of fuel and thus reduces harmful tailpipe emissions. It also reduces particulate emissions. In recent years, growing attention has been devoted to the conversion of biomass into ethanol and significant advances have been made towards the technology of ethanol fermentation. Ethanol can be produced from any biological feedstock that contains appreciable amounts of sugar or materials that can be converted into sugar such as starch or cellulose (Manochio *et al.*, 2017). The process of ethanol production from lignocellulosic biomass involves three major steps, which are pretreatment, enzymatic hydrolysis, and fermentation as shown in Fig. 3. Biomass is pretreated to improve the accessibility of enzymes. After pretreatment, biomass undergoes enzymatic hydrolysis for conversion of polysaccharides into monomer sugars, such as glucose and xylose. Subsequently, sugars are fermented to ethanol by the use of different micro-organisms. The solid residue from the fermentation process can be used as cattle feed.

The choice of biomass is important as feedstock costs typically make up 55%–80% of the final alcohol price (Kulkarni and Dalai, 2006). Raw materials containing sugars, or materials that can be transformed into sugars, can be used as fermentation substrates. The fermentable raw materials can be grouped as directly fermentable sugary materials, starchy, lignocellulosic materials, and urban/industrial wastes. Sugar-containing materials require the least costly pretreatment. But, starch-based biomass is usually cheaper than sugar-based materials but requires additional processing. On the other hand lignocellulosic materials (such as wood and straw) are readily available. But, the conversion of lignocellulosic biomass is more complex due to presence of long-chain polysaccharide molecules, which require enzymatic hydrolysis before resulting in sugar for fermentation.

Due to rapid growth in population and industrialization, worldwide ethanol demand is increasing continuously. Conventional crops such as corn and sugarcane are unable to meet the global demand of bioethanol production due to their primary value of food and feed. Therefore, in recent years, more attention has been given to lignocellulosic biomass like forest residue, agriculture waste, industrial residues, and municipal waste, which could be used as ideally inexpensive biomass materials for production of ethanol by fermentation. Bioethanol production from rice straw, wheat straw, corn straw, and sugarcane bagasse is a matter of interest worldwide now. Rice straw is the most abundant waste, and has the potential of producing the maximum amount of ethanol among these four mentioned agricultural wastes.

Thermochemical Conversion

Thermochemical conversion may of three types: Pyrolysis, gasification, and combustion, as discussed in detail below.

Pyrolysis

Pyrolysis is a thermochemical conversion process in which volatile component of a solid biomass is vaporized by heating without presence of any oxidizing agent and leaves behind a residue consisting of char and ash. The condensable part of pyrolysis vapor is collected as a liquid after condensation, which is commonly known as biooil and the remaining noncondensable gases leaves the system can be used as fuel gas. The main objective of pyrolysis process is to produce as much liquid fuel from biomass s possible. Liquid fuel has a number of advantages over gaseous fuel like storage, transportation, and versatility in application such as IC engine, boilers, turbines, etc. The product distribution of the biooil depends upon the amount of cellulose, hemicellulose, and lignin present in biomass (Mythili *et al.*, 2013). It was observed from the literature that the decomposition of hemicelluloses,

cellulose and lignin occur at 220–315°C, 314–400°C, and 160–900°C respectively. In addition to the quantitative composition of cellulose, hemicelluloses, and lignin in biomass, the interaction between these components also determines the product distribution in the biooil. The nature of pyrolysis product depending upon the operating conditions used like temperature, heating rate, residence time, pressure, catalysts etc. For example, high temperatures and short residence times favor the formation of condensable products, while high temperatures and longer residence times favor the formation of noncondensable gaseous products. Depending on the operating conditions, the pyrolysis process can be classified into three categories: Fast pyrolysis, intermediate pyrolysis, and slow pyrolysis (Dhyani and Bhaskar, 2018). Recently, pyrolysis of biomass has gained more attention compared with combustion and gasification because of its above-mentioned advantages. Different types of reactors are used by the researchers to carry out different pyrolysis processes, such as fixed bed reactor, fluidized bed reactor, rotating cone reactor, vacuum reactor, auger reactor, etc. However, it is still at an early stage in development and more research and development works are needed to overcome the technical and economic issues to compete with traditional fossil fuel-based techniques.

Fast pyrolysis

Fast pyrolysis is an advanced process where biomass is heated rapidly in controlled temperature to result in high yields of biooil. In fast pyrolysis, the production of biooil can be obtained as high as 80 wt% on dry feed. The essential features of a fast pyrolysis process are given below.

- Very high heating and heat transfer rate are required.
- Nearly ground biomass feed is needed for fast conversion.
- Carefully controlled temperature.
- Rapid cooling of the pyrolysis vapors to maximize the biooil production.

The typical heating rate in fast pyrolysis varies from 100 to 1000°C/s and the residence time is 1–2 s. It is carried out at moderate temperature of 450–600°C. It is reported in the literature that the liquid yield as high as 75% on dry feed basis can be obtained in fast pyrolysis of wood (Bridgwater *et al.*, 2009).

Intermediate pyrolysis

Intermediate pyrolysis is similar to fast pyrolysis process but has a bit longer residence time (10–20 s). The main objective of intermediate pyrolysis is to use more hard-to-handle feedstock such as sewage sludge, grass, or algae. Intermediate pyrolysis offers working conditions preventing formation of high molecular tars and offers dry and brittle chars suitable for fertilization or combustion. In this type of processing, larger sized feedstock may be used without milling. This offers the opportunity to separate char from vapors easily.

Slow pyrolysis

In slow pyrolysis, the heating rate is very slow and the process is carried out for relatively longer residence time. Slow pyrolysis is carried out in the temperature range from 400 to 800°C. Heating rates as low as 0.1–2°C, have been reported (Antal and Grønli, 2003). The slow pyrolysis process may continue from few hours to a number of days. Here the main objective is to produce biochar from biomass. Generally, vapor is not condensed in this process but it can be used for providing heat required for the pyrolysis process through combustion. Biomass with large particle size can be used provided the feeding system can handle it. Slow pyrolysis process is more tolerant to the moisture content in biomass compared with fast pyrolysis and intermediate pyrolysis process.

Therefore, higher temperatures and longer residence time promote gas and vapor production, while higher char yield is obtained at lower temperatures and slower heating rates. The product slate is similar for each feedstock at a given temperature, although the yields of gas, pyrolysis oil, and char can be quite different. Table 1 shows the comparison between three different pyrolysis processes.

Gasification

Biomass gasification is the thermochemical conversion of solid biomass into the fuel gas, which contains mainly hydrogen, carbon monoxide, carbon dioxide, methane, and nitrogen. A limited supply of oxygen, air, steam, or a combination of these serves as gasifying agent. Fuel gas produced from biomass gasification can be used in boiler, gas engine, gas turbine, etc. In general, three

Table 1 Comparison of fast pyrolysis, intermediate pyrolysis, and slow pyrolysis

Parameters	Fast pyrolysis	Intermediate pyrolysis	Slow pyrolysis
Heating rate	> 100°C/s	> 10°C/min and < 100°C/min	< 10°C/min
Operating Temperature	~ 500°C	~ 500°C	~ 400°C
Residence time	1–2 s	10–20 s	Hours to days
Biooil	75%	50%	30%
Biochar	12%	20%	35%
Fuel gas	13%	30%	35%

Fig. 4 Schematic diagram of fixed bed gasifiers.

different gasification technologies are used for biomass gasification: Fixed bed, fluidized bed, and entrained bed (Loha *et al.*, 2018a,b). The principle of operation, merits, and demerits of different types of gasifiers are described below.

Fixed bed gasification:

Depending upon the way the solid fuel and the gas interact, the fixed bed gasifiers are classified into three types: Updraft, downdraft, and crossdraft gasifiers. Fig. 4 shows the schematic diagram of fixed bed gasifiers. In an updraft gasifier (Fig. 4(a)) air passes through the biomass from the bottom and the product gas comes out from the gasifier at the top. As the oxidant is supplied at the bottom, the exothermic combustion reactions take place there. Therefore, the highest temperature is at the bottom for updraft gasifier. From the bottom to the top the temperature decreases. Hence, the fuel enters at the top and there is first a drying zone, then the pyrolysis zone, reduction zone, and finally the oxidation zone, before the remaining ash is removed from the reactor (Basu, 2006). The produced gas moves upward through the fixed bed of solids. It transports the heat from the hot combustion region to the inlet region of the solids. Thus it cools down so that the main problem for the updraft gasifier is the high tar content in the produced gas, as the tar once formed is not cracked in the reactor.

In comparison, the product gas from a downdraft gasifier has the lowest tar content received. The fuel enters the reactor again at the top and moves downward. The gas is added some way down the fuel path where the reactor cross section is narrowed (Fig. 4(b)). It moves concurrent with the particles downward to the grate at the bottom where the product gas and also the ash are retained. So not only the fuel but also the pyrolysis gas produced passes the oxidation zone. Therefore, the tars can be cracked and the tar content of the product gas is very low (Basu, 2006). The drawback of the downdraft gasifier is the high demand on the fuel particle size and carbon conversion is lower than in other gasifier types.

In crossdraft gasifier (Fig. 4(c)), the fuel is introduced from the top and the air from the side of the gasifier. The fuel moves down as it gets dried, devolatilized, pyrolyzed, and finally gasified, while the air exits from opposite side of the unit. The exit for the gas is more or less at the same level as that of entrance. The combustion and gasification zone is located near the entrance of the air while the drying and pyrolysis zones are at a higher level than the entrance and exit. Although the crossdraft gasifier has certain advantages over updraft and downdraft gasifier, it poses serious limitations. The disadvantages such as high exit gas temperature, poor CO₂ reduction, and high gas velocity are the consequence of the design. Unlike downdraft and updraft gasifiers, the ash bin, fire, and reduction zone in crossdraft gasifiers are separated. These design characteristics limit the type of fuel for operation to low ash fuels such as wood, charcoal, and coke. The load following ability of crossdraft gasifier is quite good due to the concentrated partial zone, which operates at temperatures up to 2000°C. Start up time (5–10 min) is much faster than that of downdraft and updraft units. The relatively higher temperature in crossdraft gasifiers has an obvious effect on gas composition such as high carbon monoxide, and low hydrogen and methane content when dry fuel such as charcoal is used.

Fluidized bed gasification:

Fluidization is the operation by which the solid particles are transformed into a fluid like state by the application of gas. In a fluidized bed gasifier, the oxidant also acts as the fluidizing agent to fluidize the inert solid particles and biomass mixture. The distinct advantages of fluidized bed over fixed bed are uniform temperature distribution in the reactor due to excellent gas–solid

Fig. 5 Schematic diagram of (a) bubbling fluidized bed gasifier and (b) circulating fluidized bed gasifier.

mixing, high carbon conversion with low tar production and flexibility in terms of fuel type, feed rate, particle size, and moisture content (Kunii and Levenspiel, 1991). Typical capacity of the fixed bed gasifier is 50–500 kW. However, due to the above-mentioned features, scale-up and operation of the fluidized bed gasifiers for electricity generation in MW scale is much easier. There are two main types of fluidized bed gasification systems: Bubbling fluidized bed and circulating fluidized bed. Fig. 5 presents the schematic diagram of bubbling and circulating fluidized bed gasifiers.

In a typical gasifier, when the gas velocity is increased, a situation is reached when the particles are just suspended in the upward flowing gas. At this situation the frictional force between a particle and fluid counterbalance the weight of particle, the vertical component of the compressive force between adjacent particles disappears, and the pressure drop through any section of the bed equals the weight of fluid and particles in that section. At this instance, the bed is considered to be at minimum fluidization. With an increase in velocity beyond minimum fluidization, large instabilities with bubbling and channeling of the gas are observed. At higher flow rates agitation becomes more violent and the movement of solids becomes more vigorous. However, the bed does not expand much beyond its volume at minimum fluidization. Such a bed is called bubbling fluidized bed (Loha, 2013). Fig. 5(a) shows the schematic of a bubbling fluidized bed reactor. In a bubbling fluidized bed, the gas velocity is low. The gas moves through the bed in the void and in bubbles with higher velocity. Some of the particles are entrained into the freeboard along with these fast moving bubbles, and some fly ash is transported with the product gas and leaves the reactor at the top. But most of the entrained particles fall back and can be continuously removed from the fluidized bed with the remaining ash at the bottom. When the gas velocity is increased further, the solids will be distributed across the whole riser height and entrained by the gas at the riser top. The particles are separated from the gas in a cyclone, and are returned to the fluid bed near the bottom. Then it becomes a circulating fluidized bed (Fig. 5(b)). The advantage of circulating fluidized beds is mainly due to the longer overall residence time. The solids circulate in the outer loop, going up in the riser, leaving at the top, going down in the return leg, and entering the riser again at the bottom. But there is also internal circulation of the solids, which fall back from the higher region of the riser and move downwards at the riser wall. The tar content from fluidized bed gasifier is less than that from fixed bed updraft gasifier, but higher compared with the tar content from fixed bed downdraft gasifier.

Entrained flow gasification:

In entrained flow gasifiers, the gas velocity is even higher than in circulating fluidized bed (Ghassemi *et al.*, 2016). Fig. 6 shows the schematic diagram of an entrained flow gasifier. No inert bed material is used. Normally, the feedstock must be in the form of very fine particles (100–400 μm). The reaction temperature is high (about 1200–1500°C) depending on whether air or oxygen is used as oxidant. Therefore, the product gas has a low content of tars and condensable gases. However, there can be problems with ash melting and reactor materials. Entrained flow gasifiers are more commonly used for fossil fuels like coal, refinery waste, etc. Their use for biomass gasification is rather limited, as it requires the fuel particles to be very fine.

Combustion

Biomass can be combusted alone in a dedicated plant, which is called direct combustion, or it can be cocombusted with coal in existing coal-based power plants, that is, cofiring, as discussed below.

Fig. 6 Schematic diagram of entrained flow gasifier.

Direct combustion:

The combustion of solid biomass is fully established and widely used in biomass applications. The combustion properties of biomass are well understood. The most popular combustors for 100% biomass applications are stoker-fired or fluidized bed designs. In stoker-fired combustors the feed burns as it moves through the furnace while resting on a stationary or moving grate. Fluidized bed designs burn the feed in a turbulent bed of inert material that is fluidized by combustion air flowing through it from underneath. Although grate-fired combustors are the form of older biomass-fired plant, fluidized bed combustors are rapidly becoming the preferred technology for biomass combustion because of their high heat transfer rate, fuel flexibility, and low NO_x emissions. Direct biomass combustion-based plants are mostly used for small-scale application in many industries as cogeneration units. But, large-scale dedicated biomass combustion plants are still not popular because of the constraint of continuous supply of the enormous amounts of biomass required for such large-scale dedicated biomass combustion plants. The availability of biomass resources is generally distributed and the transportation cost for such enormous amounts of biomass to a centralized location where the plant is located becomes the major factor. Therefore, instead of dedicated biomass plant, cofiring of biomass to the existing power plants has emerged as a more economical short-term option for biomass utilization.

Cofiring:

Cofiring is the process of burning two different types of fuel simultaneously to generate heat or electricity. Cofiring of biomass in coal-based power plants is generally done to get environmental benefit by using renewable energy without significant cost involvement. Compared with dedicated biomass-based plants, the addition of biomass to the high efficiency coal-fired power plants can greatly increase the efficiency of utilizing biomass (Baxter, 2005). Besides, the cost of retrofitting an existing coal-fired power plant for biomass cofiring is significantly lower than building a new dedicated biomass-based power plant (Spliethoff and Hein, 1998). Recently, the interest in cofiring has grown due to increasing concern about global warming and GHG emissions leading to new policies on energy and the environment to reduce emissions. Cofiring is regarded as the most attractive short-term option for replacing coal used for power generation with renewable fuels at lower costs to result in direct decrease of greenhouse gas emissions. There are many advantages of cofiring of biomass in coal-based power plants and some of the important advantages are discussed below (Verma *et al.*, 2017).

- Cofiring of biomass is the easiest way to increase the use of biomass for power generation.
- Cofiring of biomass to the existing coal-fired power plants can be done with little modification which implies little investment cost.
- Opportunity of using different biomass materials with coal, which can diversify the fuel portfolio in existing coal-fired power plants.
- In case of coal shortage, import substitution with biomass will significantly improve the economy of the nation.
- It will lower the CO₂ emission by saving the fossil fuels.
- It will also reduce other airborne emission like NO_x and SO_x because most of the biomass contains less nitrogen and sulfur.

Fig. 7 Schematic diagram of direct cofiring.

- It will provide energy security to the nation by producing electricity from locally available fuel like biomass.
- Growing of biomass as energy crops will add value to barren lands, improve the landscapes, conserve soil resources, and reduce the need for water and fertilizers.

Cofiring of biomass is more cost-effective in combined heat and power (CHP) plants, which generate electricity and useful thermal energy. CHP, also known as cogeneration, is often used in industrial facilities where there is specific demand for both heat and power. The economics of biomass cofiring is increased when it is used in CHP plants because of higher overall efficiency in CHP compared with normal power plants. Cofiring of biomass to the existing coal-based power plants yields negative CO₂ emission to the atmosphere when it is combined with carbon capture and storage technology. Cofiring of biomass to the coal-fired power plants can be done in three different ways. If biomass is combusted directly with coal then it is called direct cofiring. In direct cofiring, combustion of coal and biomass takes place simultaneously at the same combustion chamber or furnace.

Direct cofiring:

Direct cofiring can be done either by premixing coal and biomass and injecting the mixture to the coal handling system or directly injecting them (without physical mixing) into the pulverize coal firing system. In case of premixing, coal and biomass can be mixed either before milling or after milling. In case of direct injection, coal and biomass are burned either using separate burners or combined burners depending principally on the biomass fuel characteristics. Direct cofiring is the simplest and least expensive method of cofiring. Hence, it is the most commonly applied cofiring configuration reported so far. However, the direct cofiring systems are more sensitive to variations in fuel quality and heterogeneity. **Fig. 7** shows the schematic diagram of direct cofiring system.

Indirect cofiring:

When biomass is converted to fuel gas in a gasifier and subsequently the fuel gas is combusted in the coal furnace then it is called indirect cofiring. It is relatively complex in arrangement and expensive compared with the direct cofiring system. Indirect cofiring can be carried out in different ways. Biomass may be burned in a separate system and the flue gas is injected to the original coal boiler or burning coal and biomass in separate systems and both the systems couple their heating fluid circuits with separate exhaust gas treatment or biomass may be converted into fuel gas in a gasifier and then the fuel gas passed through the coal boiler. Indirect cofiring reduces the problems associated with corrosion, fouling, and slagging, as the biomass is not fed directly to the furnace. Therefore, the indirect cofiring system has the advantage of better fuel flexibility than direct cofiring and it also allows larger amount of biomass cofiring than the direct system. **Fig. 8** shows the schematic diagram of an indirect cofiring system.

Parallel cofiring:

If biomass and coal are combusted in separate furnaces and generate steam separately then it is called parallel cofiring. In parallel cofiring, separate combustion chambers and boilers are used for coal and biomass. Steam produced by both the boilers are fed into the main power plant system where steam is upgraded to higher temperatures and pressures to give higher energy conversion efficiencies. Therefore, the fuel preparation and feeding system is physically independent here. Parallel cofiring system offers more opportunity for using higher percentages of biomass fuels compared with the direct and the indirect cofiring systems (Thompson, 2006). Here, the maximum amount of energy that can be generated from biomass will depend on the downstream infrastructure of the existing plant such as for steam turbines. Like indirect cofiring, biomass ash is separated from coal ash in parallel cofiring, which allows using a wide variety of biomass. However, the parallel cofiring system is much more expensive than direct and indirect cofiring systems because of additional infrastructure requirements. Parallel cofiring technique is mostly used in the paper and pulp industries. The schematic diagram of parallel cofiring is shown in **Fig. 9**.

Fig. 8 Schematic diagram of indirect cofiring.

Fig. 9 Schematic diagram of parallel cofiring.

Physical Conversion

In the physical conversion process, oil is extracted mechanically by squeezing the seeds of various biomass seeds. The process produces not only oil but also a solid residue called deoiled cake, which can be used for animal fodder. The oil extracted is further processed by reacting with alcohol using a process called esterification to obtain biodiesel. Biodiesel can be a potential alternative to petroleum diesel. It has a number of advantages, for example, it is nontoxic, it degrades four times faster than diesel, it has higher flash point, it contains no sulfur, etc. Emissions of (PAH) compounds are substantially lower with biodiesel. Initially, biodiesel is produced from edible oils in most of countries. But, converting edible oils into biodiesel means converting food resources into automotive fuels. Therefore, it is envisaged that large-scale production of biodiesel from edible oils may bring global imbalance to the food supply and demand market. Therefore, the focus has shifted from edible oil to nonedible seeds like *Jatropha curcas*, *Madhuca indica*, *Pongamia pinnata*, etc. But, the expansion of nonedible oil crop plantations for biodiesel production on a large scale may increase deforestation. Moreover, it may also happen that the land that would otherwise have been used to grow food will be used to grow fuel and this trend is already being observed in many parts of the world. In that situation, biodiesel production from animal fat or waste oil from restaurants may be a good option. However, these limited resources may not meet the increasing demand of biodiesel. Recently, the research and development throughout the world have been focused to generate biodiesel from lignocellulosic biomass residues.

Properties of Biomass Affecting the Conversion Process

Properties of biomass are important for converting biomass into other forms like fuels, heat, and power. These properties include bulk density, particle density, particle size, moisture content, volatiles content, fixed carbon, ash content, and heating value.

Biomass materials are mostly available in loose form. Therefore, the bulk density of biomass is an important parameter for designing the biomass handling system in biomass processing unit. Bulk density is defined as the weight of biomass material in bulk per unit volume. The bulk density of loose biomass varies from 60 to 150 kg/m³. The nonuniform particle size and shape of

the raw biomass materials in loose form have very low bulk density, which leads to high costs for transportation, storage, and feeding into the processing plant. Besides, if biomass materials in their loose form are converted to energy, they will create more pollution by emitting fine particulate matter to the atmosphere. Therefore, loose biomass materials are generally densified by making briquettes before using for conversion. Since briquettes are created by compressing loose biomass materials, they are denser, harder, and more compact. The bulk density of briquettes varies from 350 to 400 kg/m³. Therefore, compacting biomass into briquettes can reduce the volume of biomass up to 70%, thus storage, transportation, and handling costs is reduced by almost 7 times, making it much easier to store and transport than loose biomass. These briquettes can readily be piled up in several heaps. They are likewise clean to handle and to be packed into bags. Thus, biomass briquettes offer a more concentrated form of energy. Along with the compactness, the heating value is increased in briquettes. Briquettes can relatively produce more intense energy than other fuel. They have longer shelf-life due to lower moisture content. Uniform physical property of briquettes leads to more efficient energy conversion.

Particle density is defined as the mass of an individual particle over its volume. Particle density for a group of particles is the ratio between mass of all particles and the volume occupied by all particles (excluding the pore space volume).

Numerous biomass materials available for energy conversion have irregular shapes. Some are of a needle shape with high aspect ratio and the finely ground particles have a round shape with aspect ratio close to 1. Therefore, the particle size range of biomass materials available from nature is huge, and may vary from microns to centimeters or even meters. However, depending on the requirement of different processes they are converted into either powder or granules or blocks.

Biomass materials generally contain a higher amount of moisture, which affects their conversion process. Higher amount of moisture in biomass materials increases the cost of production in any biomass conversion process. Therefore, it needs to be dried properly before being used for any conversion process.

Volatile matter is the amount of the gases formed except water vapor while biomass material is heated in an oxygen-free environment. The volatile matter from biomass generally contains hydrogen, carbon monoxide, carbon dioxide, hydrocarbons, and nitrogen dioxide. After realizing the volatile matter, the remaining solid combustible residue is called the fixed carbon and remaining noncombustible residue is called ash. The quality of biomass for thermochemical conversion depends upon the amount of volatile matter, fixed carbon, and ash contained in the biomass. Volatile matter has the opposite trend of fixed carbon. Generally, biomass contains higher amount of volatile matter and lower amount of fixed carbon compared with coal. The ash content in biomass has special significance because it causes lots of operational problems during biomass combustion. For example, silicon from biomass ash is the main contributor to wear. Potassium and calcium cause fouling of heat exchangers and slagging in the bottom of the furnace. This requires shutting down the units regularly, reducing the operating time of the production units and also increasing the maintenance cost. The calorific value is the amount of heat released from unit mass of biomass while it is burned with oxygen. It is the indicator that determines the amount of energy that can be recovered during its thermochemical conversion. The calorific value depends upon the amount of combustible present and different elements present within the combustible in biomass. [Table 2](#) shows the ultimate and proximate analysis of different biomass materials.

Effect on Global Warming by Using Biomass as Energy Source

Coal, oil, and natural gas are the three different forms of fossil fuels that are widely used in the electricity generation, transportation, and chemical industries. Large-scale use of fossil fuels started around the Industrial Revolution. Today, these are the most

Table 2 Proximate and ultimate analysis of different biomass materials

Fuel	Proximate analysis				Ultimate analysis				
	Volatiles	Fixed carbon	Moisture	Ash	C	H	O	N	S
Pine	71.50	16.00	12.0	0.50	51.60	4.90	42.60	0.90	n.d.

widely used sources of energy available for the use of both personal as well as commercial purposes. To date, almost three-fourths of the demands of the energy in the world is fulfilled by fossil fuels. Combustion of these fossil fuels emits gases, mainly carbon dioxide (CO₂), sulfur oxides (SO_x), nitrogen oxides (NO_x), chlorofluorocarbons (CFCs), and other trace gases. Most of the gases emitted during combustion, known as greenhouse gases, are considered to be detrimental to the Earth's atmosphere as these gases absorb radiation within the thermal infrared range and then reradiate it back to the surface resulting in an elevation of Earth's surface temperature, which is known as global warming. Among different gases, the gas considered to be contributing the most to the GHE is CO₂ because of two factors: (1) CO₂ represent the largest emissions of all global anthropogenic GHG emissions (around 75% of all GHGs), and (2) CO₂ has a very high residence time in the atmosphere. Hence, CO₂ is the most important anthropogenic greenhouse gases of our concern. The global atmospheric concentration of CO₂ has increased to 408 ppm in 2018 (NOAA, 2018). The concentration of CO₂ increased every year since scientists started measuring the slopes of the Mauna Loa volcano more than five decades ago. The rate of increase has accelerated from about 0.7 ppm per year in the late 1950s to 2.1 ppm per year during the last decade and now the rate of increase is 100 times faster than the increase that occurred when the last ice age ended. Therefore, it is felt worldwide that mitigation of GHGs is essential as soon as possible. Use of biomass as an energy source will definitely have a positive effect on environment because of its low CO₂ and SO₂ emissions. CO₂ is the major contributor to GHG emission and SO₂ is the main reason for acid rain. Hence, there is a worldwide trend toward increasing the use of biomass as an energy source in different ways. Using biomass as fuel for energy generation through different routes has many advantages. For example, biomass combustion or cofiring with coal is an attractive option with a relatively low need for additional investments when used in the power generation sector. The use of biomass in power generation instead of fossil fuels will result in significant decrease in the release of particulate matters to the atmosphere because of low ash content in biomass (2%–6%) compared with coal (20%–50%). Sulfur emission is also reduced compared with fossil fuel because of low sulfur content in biomass. Utilizing biomass wastes for biogas production through anaerobic digestion or production of ethanol via fermentation prevents the accumulation of these wastes and eliminates their cause of serious environmental concerns. The use of animal dung to produce biogas by controlled anaerobic digestion can solve the environmental issues concerning GHGs, nitrogen, and unpleasant odors. It also helps in intensifying the recycling of nutrients within agriculture. Further, biogas has lower carbon to hydrogen ratio and it is a better fuel than these wastes and is a much cleaner, odorless, and smokeless fuel that can be used for household cooking, heating, and lighting requirements. Similarly, ethanol produced from biomass fermentation can serve as the cleanest liquid fuel alternative to fossil fuels. In gasification, syngas is produced from biomass, and can be used to run internal combustion engines, as a substitute for furnace oil in direct heat applications, and to produce methanol – An extremely attractive chemical that is useful both as fuel for heat engines as well as chemical feedstock for industries.

However, to precisely calculate the net CO₂ emission from biomass energy, it is necessary to monitor and observe the whole carbon cycle caused by the biomass energy development and consumption. For example, deforestation or destroying local vegetation to grow crops and thereafter producing energy from those crops will result in larger net CO₂ emission than the fossil fuel. Nevertheless, utilizing locally available biomass or agricultural waste or forest residues for generating bioenergy will reduce CO₂ emission.

Potential of Biomass to Meet the Global Bioenergy Demand

Global production of biomass and biofuel is growing rapidly due to the increasing price of fossil fuels, concerns over greenhouse gas emission and carbon footprint, and considerations regarding the security and diversification of energy supply. The ways biomass is currently used will not continue for long and are expected to change significantly in the next few years. At present, traditional methods of space heating and cooking, such as burning firewood, account for two-thirds of total biomass use. But, in the near future, this would give way to modern biomass consumption, including substantially larger shares for power and transport applications. The global biomass potential is sufficient to meet the growing demand. It is estimated that the total biomass supply worldwide in 2030 could range from 97 to 147 EJ/yr among which about 38%–40% would originate from agricultural residues and waste and the remaining supply potential is shared between energy crops and forest products, including forestry residues (IRENA, 2014). Recently, there have been a number of studies performed to estimate the future demand and supply of biomass. The availability and expected future potential of major biomass producing countries are discussed below. Biomass is one of the largest renewable energy resources in sub-Saharan Africa (SSA). About 90% people in SSA use biomass, such as wood or residues, for cooking and heating which means about 265 million tons of wood equivalent of energy is required for cooking. The estimated forest residues available in SSA comprise about 444 million tons and the crop residues comprise about 140 million tons. Therefore, the power generation potential by using 30% of agroresidues and 10% of forest residues is 5000 MW and 10,000 MW respectively (Stecher *et al.*, 2013). In the United States, it is estimated that the demand for biomass in 2030 will be 100 million tons if the state Renewable Portfolio Standards (RPSs) are implemented and it will reach to 262 million tons if the federal Renewable Fuel Standard (RFS) is implemented. The crop and forest residues could meet more than 70% of the demand under the policy scenarios considered above. The remaining supply of biomass can be achieved by converting 0.7 million hectares of land under the RPS and 4.3 million hectares of land under the RFS (Oliver and Khanna, 2017). A study on the potential availability of biomass resources in Brazil shows that it produces around 1500 million tons of biomass and it is expected to increase to 2500 million tons by 2030. The bioenergy potential from Brazilian Resource is 8902.2 EJ, which will increase to 17,299 EJ by 2030 (Welfle, 2017). Biomass is a significant source of energy in China, particularly in rural areas. In China, the total amount of annual residue biomass, averaged over 2003–2007, is around 15.519 EJ among which 10.818 EJ comes

from agriculture residues (70%) and 4.701 EJ from forestry residues (30%). Total 12.693 EJ of biomass is available for energy production, with 66% derived from agricultural residue and 34% from forestry residue. Most of the available residue comes from south central China (3.347 EJ), east China (2.862 EJ) and southwest China (2.229 EJ) (Gao *et al.*, 2015). India is also blessed with substantial biomass resources. The estimated annual biomass production in India is 500 million tons, which can generate around 17,500 MW power. In addition, around 120–150 million tons of surplus biomass can be collected from waste of various industries, which can generate another 5000 MW power (Loha, 2013). A broad assessment of the potential availability of biomass in Australia reveals that approximately 80 million tons/yr of biomass are available with the major contribution from crop stubble (27.7 million tons/yr), grasses (19.7 million tons/yr), and forest plantations (10.9 million tons/yr) (Crawford *et al.*, 2016). It is also estimated that over the next 20–40 years, total potentially available biomass could increase to 100–115 million tons per year, with new plantings of short-rotation trees being the major source of the increase. In the European region, the bioenergy potential from dedicated bioenergy crops varies between 1.7 and 12.8 EJ/yr. In addition, agricultural residues and forestry residues can potentially add 3.1–3.9 EJ/yr and 1.4–5.4 EJ/yr respectively (De-Wit and Faaij, 2010). However, large variation exists in biomass production potential and costs. Regions that have high potential and low costs are large parts of Poland, the Baltic States, Romania, Bulgaria, and Ukraine. On the other hand, regions like Western Europe, France, Spain, and Italy are moderately attractive following the low cost high potential criterion. Biomass could also play a major role in Russia to increase its renewable energy share by 2030. Renewable energy consumption could rise from 3.6% of the current energy mix to more than 11% by 2030. It is estimated that the demand of bioenergy in Russia could reach 2.4 EJ by 2030 whereas the country has the potential to supply up to 14 EJ per year from biomass feedstocks (IRENA, 2014).

Conclusion

It is observed from the above study that biomass has the significant potential of mitigating greenhouse gases and carbon footprints if it is used scientifically. There are three different processes by which biomass can be converted into useful energy, namely biochemical, thermochemical, and physical conversion. All the conversion processes have their merits and demerits. Biochemical processes have the advantage of low energy requirement for operation. But the main drawback is that the biochemical processes are very slow. Whereas, thermochemical conversion processes are very fast. Any type of biomass can undergo thermochemical processes whereas only selected biomass materials can be processed through biochemical and physical routes. Hence, thermochemical routes of biomass conversion are much more attractive. Among thermochemical processes, cofiring of biomass with the existing coal-based power plants is the most promising near-term application of biomass. On the other hand, biomass gasification with sophisticated downstream application like gas turbine/fuel cell and biomass pyrolysis with upgradation of biooil offer the greatest potential for developing countries. Therefore, different types of gasifiers are developed and used for gasification of biomass. However, under present conditions, economic factors seem to provide the main constraint for wider application of biomass gasification. In many situations where the price of petroleum fuels is high or supplies are unreliable, the biomass gasification can provide an economically viable system, provided the suitable biomass feedstock is easily available.

Renewable Electricity Generation – Effect on GHG Emission

Avishek Ray and Sudipta De, Institute of Engineering and Management, Jadavpur University, Kolkata, India

Introduction

Energy is the basic need for human civilization. Men started harnessing energy from ancient days by burning dried leaves, logs of wood etc. Heat generated was mostly used for roasting meat. Conversion of heat to work or movement subsequently transformed the human civilization to a new dimension. Men began to use energy for locomotion. Subsequently the industrial revolution happened. It was the age of automation when the human power or the animal power was replaced by the “power of machines”. Electricity is the most convenient and useful form of secondary energy in the modern world. It can be transported over a long distance with high efficiency and then may be converted into all other forms of energy with suitable conversion technologies. Moreover, the electrical gadgets can be controlled more precisely than the thermal gadgets. However, being a secondary form of energy, it has to be generated from some other naturally available energy resources, called primary energy. Demand for electricity is ever increasing with increased population and improvement of living standard. From the beginning till date electricity is mostly generated from the combustion of fossil fuels like coal, oil, gas etc. These fossil fuels were created by conversion of submerged biomass under the ground over a long period. These are all basically hydrocarbons in different forms with some other combustible and incombustible materials. The combustible parts of these hydrocarbons are both hydrogen and carbon. Heat energy is released from these hydrocarbons through oxidation of both of these. For maximum energy release from these fuels, complete combustion of both hydrogen and carbon is desired. Hydrogen is converted to water vapor during its complete combustion which has almost no effect on the environment and the living ecosystem as a whole. However, the product of complete combustion of carbon of the fossil fuel is carbon dioxide (CO_2) which is released to the atmosphere from the fossil fuels stored under the ground in this process. Like many other gases, CO_2 in the atmosphere has a special effect of reflecting back the emitted radiation from the earth and thus retaining more heat from the sun in the atmosphere. This leads to the rise in average temperature of the earth's atmosphere. As the effect is similar to trapping of heat in greenhouse during winter, this effect is called the greenhouse effect and CO_2 is one of such greenhouse gases responsible for this effect. As electricity has been generated over centuries using mostly fossil fuels, CO_2 concentration in the atmosphere has increased in this process of power generation from fossil fuels, leading to observed increase in average atmospheric temperature. This is formally called ‘global warming’. It has several disastrous effects on the environment and the most critical among those is the rise of sea level due to melting of polar ice. In fact, global warming is considered to be the most critical threat to human survival including many other species on the earth. As this anthropogenic CO_2 emission is leading to a possible destruction of human civilization and even living on earth, several measures are adopted internationally beyond political boundaries to fight this menace. Intergovernmental Panel on Climate Change (IPCC) assess the effects of global warming regularly, suggest measures to be adopted and possible future scenario with different measures adopted through international negotiations in different conventions. Different conventions in this regard initially suggested possible measures to be adopted to mitigate climate change only. However, over the years it was realized that more meaningful measures would be towards overall ‘sustainable development’ rather than addressing climate change only as an isolated phenomenon. According to the report of the United Nations’ Brundtland Commission, sustainable development is defined to be “the development that meets the demand of the present generation without compromising the need of the future generations.” Supplying ever increasing need for electricity is one of the critical challenges for sustainable development. Presently, the whole world is mostly dependent on fossil fuels like coal, oil, natural gas etc for energy generation. Presently 38% of the world's primary energy consumption is from oil followed by coal (24%) and the rest comes from natural gas, nuclear and renewable (Tester *et al.*, 2006). The fossil fuels emit carbon dioxide and other greenhouse gases in the process of combustion as shown in Fig. 1. The generation of power is mostly dominated by coal and oil. The share of each type of fuel in the global energy mix is shown in Fig. 2. Presently, the power sector is the single largest sector for the emission of GHG amongst all the sectors owing to the maximum use of these fossil fuels. On the other hand, electricity from the renewable resources generally does not generate greenhouse gases during operation, though installation and final disposal of some such plants may cause some GHG emission. So, more use of renewable electricity will definitely reduce the emission of these harmful gases thereby reducing the detrimental effect on human survival. Also per capita energy consumption is grossly related to the living standard and gross domestic product (GDP) of a nation. Per capita energy consumption is generally much higher in the developed countries than in the developing countries. For example, per capita electricity consumption in India is 805.60 kWh whereas that of USA is 12,984 kWh in the year 2015 which is almost four times the world average of per capita electricity consumption. But still India is the fourth largest emitter of GHG gases in the world due to its huge population and mostly fossil fuel based electricity generation (World Bank, 2018). As energy sector is one of the largest contributors of the global GHG emission, various means have to be thought out to reduce the GHG emission from this sector. The energy sector emits about 400 Mt of CO_2 /year (European Commission, 2018). Proper energy management i.e., planned, efficient and judicious use of energy and more use of renewable energy are considered as the two most suitable options for the reduction of GHG.

Fig. 1 GHG emission from combustion of fossil fuels.

Fig. 2 Percentage share of different energy resources in the global energy mix.

International Initiatives for the Reduction of GHG Emission and Identified Relevance of Renewable Energy Introduction

The reduction of the GHG emission was a global concern for every stakeholder since the onset of the 20th Century. All countries need to work together for reducing the GHG emission and meeting the target to protect the earth. With this view, global leaders negotiated in joint meetings to decide committed action plans to mitigate the climate change with possible minimum compromise with their national economic growth, if any. As effects of GHG emission is global, though sources may be local, climate change has to be addressed globally beyond political boundaries and actions may be either local or global. In order to reach consensus on scientific facts of climate change, an Intergovernmental Panel on Climate Change

Table 1 Some important international climate change mitigation initiatives

Serial no.	Protocol name	Place	Year	Main feature
1	Kyoto Protocol	Kyoto, Japan	1997	Emission targets were set to the participating nations.
2	Cancun Agreements	Mexico	2010	It was decided that the developed nations will mobilize 100 billion USD to developing nations as climate protection fund.
3	Durban Platform for enhanced Action	South Africa	2011	Opinion of legal framework formulation was considered to all members of the United Nations.
4	Paris Agreement	Paris, France	2016	The climate change is considered as an urgent threat. The specific areas of fund and technology transfer of the developing nations are identified.

(IPCC) was formed in 1988. Renowned multi-disciplinary experts from many countries are working in IPCC. Function of IPCC is to scientifically monitor, assess climate change, disseminate these facts for the public and recommend possible measures with specific target of maximum rise of average temperature over a specific period. This assessment and recommendations need interdisciplinary experts to study interrelated effects. Also actions have several impacts on individual countries depending on their socio-economic conditions. Specifically actions to mitigate climate change have economic impacts in most cases and poor countries are affected most with it. The diplomatic negotiations are thus very important for actions of climate change. According to the assessment of the IPCC, increase in use of renewable energy replacing fossil fuels is a possible option for reducing GHG emission. Though electricity generation with fossil fuels may not be replaced in very near future, the same with carbon capture and storage may be the possible option to reach acceptable target of maximum CO₂ emission. Unfortunately, the technology of CO₂ capture from the power plants is still cost intensive process and even affects the efficiency of the overall plant leading to increase in cost of electricity significantly. Moreover, the storage of captured CO₂ at a high pressure needs to be explored more for future possible catastrophes. On the other hand, reducing GHG emission through renewable electricity generation is a rather safer path and will also add better long term energy security and sustainability. For reducing the GHG emission, more use of renewable energy is inevitable. But the initial cost of installation of the renewable energy devices is also generally high. This is a major issue against wide acceptance of renewable energy systems. So, in most of the international conventions, decisions were taken to incentivize the introduction of renewable energy projects through competitive financing. This helped adoption of renewable energy projects more rapidly. Some of the landmark international conventions for collective negotiations of most of the countries of the world to identify possible committed/voluntary actions to address the climate change issue are listed in [Table 1](#). The first important convention was the Kyoto protocol in 1997. In this protocol only the emission targets were set but the means to reduce the emission was left to the stakeholders and no monetary incentive was also decided in this protocol. The next significant convention was the Cancun Agreements. In this agreement it was decided that the developed nations will fund the carbon emission mitigation projects of the developing nations. In spite of these accepted resolutions, responses from the stakeholders were not commendable. So, in the next international convention, i.e., Durban Platform for enhanced action, a legal framework was constituted and there was a provision for measures to be taken against a nation or a stakeholder if the committed target was unmet. There was a legal framework to bring all the countries to a “renewable power target” phasing out the fossil fuel options. From this meeting emerged the concept of “Renewable Power Purchase Obligation Issues”. This made it compulsory for all stakeholders to implement renewable energy projects. In these meetings the use of renewable power was recognized as a potential way to mitigate the GHG emission targets. The next convention was Paris Agreement. In this agreement, climate change was considered as an urgent threat to the entire world. Here, specific areas were identified where the technology transfer or the fund transfer might take place in between the developed nations and the developing nations for the promotion of carbon free energy. The next summit was COP 21. This Conference was held in Paris, France and this was a convention where the issue of sustainable development was emphasized. The specific areas were identified where the technology growths as well as financial incentives were required to make the development sustainable in the long run. From these conventions the concept of low carbon business models like carbon trading, renewable energy certificates, power purchase obligation and many others emerged. These business models have catalyzed the growth of renewable energy projects as a potential means for mitigating GHG emission. The monetary benefit comes from the government incentives and also there is very low operational cost, if any, as most of the renewable resources like solar, wind etc., are available in the nature at no/low cost. Presently, with rapid development of renewable technologies and suitable policy adoption, payback periods for most of the renewable energy projects are below five years. The urgent need for increased use of renewable energies replacing fossil fuel based energies to reduce carbon emission is now accepted as an international mission through global cooperation.

Relation Between Conventional Electricity Generation and GHG Emission

For conventional electricity generation, fossil fuels are combusted to release heat energy. In this process, GHG and a number of harmful effluents for the environment are also emitted. The fossil fuels are mainly the long chain hydrocarbons and containing

Fig. 3 Products of combustion of fossil fuels.

Fig. 4 Pollution effects caused by the combustion of fossil fuels.

sometimes some amount of sulfur, nitrogen oxygen too. Also some incombustible component, called ash, is also present in solid fossil fuel, i.e., coal. Through gasification and partial combustion, the carbon gets oxidized to form carbon dioxide, carbon mono oxide and even small amount of methane. These are greenhouse gases causing global warming. On the other hand, sulfur and the nitrogen compounds get oxidized to form harmful gases like sulfur dioxide and nitrogen dioxides which not only causes global warming but also have other environmental detrimental effects like acid rain etc., **Fig. 3** shows the relationship between the electricity generated and the effluents produced. The combustion of the hydrocarbons is an exothermic reaction. Here, the heat is released along with the oxides of carbon and hydrogen. The oxide of hydrogen i.e., water vapor is released in the atmosphere but it has no harmful effect. But the oxides of nitrogen, hydrogen and sulfur have environmental degradation effects causing multiple problems like global warming, diseases to humans etc. The dust particles and other by products of the energy generation have adverse effects on the ambient air quality of the environment. The possible effluents from the different fossil fuel based power plants are greenhouse gases like CO_2 , CH_4 , N_2O . **Fig. 4** shows the possible environmental hazards which may take place due to the generation of energy from the different types of fossil fuels. The GHG emission potential of different renewable fuel based power plants is shown in **Table 2** (Agarwal *et al.*, 2013). It has been noted that the GHG emission potential of the renewable energy systems is much less than that of the fossil fuels. **Table 3** shows the comparative analysis of the GHG emission potential of common fossil fuel based power plants. It is observed that the emission potential of renewable energy resources is much less than

Table 2 Emission potential for renewable based power plants

Serial No	Name of component	Emission potential (g-CO ₂ /kWh)
1	Solar photovoltaic	98
2	Biogas system	70
3	Wind	100
4	Fuel cell	20
5	Biomass gasifier systems	65

Table 3 Emission potential for fossil fuel based power plants

Serial No	Name of component	Emission potential (g-CO ₂ /kWh)
1	Coal	950
2	Natural gas	455
3	Oil	600

**Fig. 5** (a) Reducing GHG emission by energy management. (b) Reducing GHG emission by use of renewable energy.

the fossil fuel based power plants. In the coal based or the oil based power plants, the fuel is fed to the furnace/chamber for the combustion. During combustion, the fossil fuels release heat as well as GHGs. The heat carried by the flue gases generated from the combustion is used to heat the working fluid of the power cycle, say water in steam power plants to generate steam from water. The steam is then used to run a turbine and generate power. So, in this system effluents and flue gases are generated during operation. So, the GHG emission potential per unit of electricity for the fossil fuel based power plants is very high. On the other hand, in case of the renewable energy based power plants the fuel is the renewable energy like solar, wind, biomass, hydro, tidal, geothermal etc. In case of solar photovoltaic cells, the electricity is generated with the help of semiconducting materials. In the solar photovoltaic (PV) cells, the light energy is directly converted to electricity. When the photons are incident on a semiconductor junction, the voltage is produced due to the barrier potential of the semiconductor device leading to the generation of a potential (voltage). Charge is also produced as electrons begin to flow leading to the flow of current. The product of the current and the voltage gives the amount of power generated by the photovoltaic modules. Thus the PV modules emit no carbon during its actual operation for generating electricity. Similarly in the solar thermal power plants the steam is produced by concentrating the solar heat by the help of suitable collectors. This heat is used to run the turbine used for generating electricity. In the wind based power generating units the wind turbine is rotated by naturally flowing wind. In biomass gasification systems, syngas is generated by incomplete combustion of biomass with sub-stoichiometric oxygen supply. Though GHGs are generated during gasification, these gases like carbon monoxide and methane are either converted subsequently or used for generating energy. Moreover biomass absorbs environmental carbon dioxide during its growth and releases the same during its gasification/combustion. So, the net carbon emission for biomass is zero, though some net 'logistic' CO₂ may be there for transportation of biomass etc. Thus it is clear

from the above discussion that the renewable resources of energy emit no/low carbon during its operation phase while generating electricity. Hence it has much low overall GHG emission potential than the fossil fuel based power plants.

Possible Means to Mitigate GHG Emission

Fig. 5(a) and (b) shows the possible means to mitigate the GHG emission. The two ways are energy management and the use of renewable resources of energy. The energy management reduces the energy consumption by the judicious use of energy. The energy management leads to maximum energy efficiency. If the energy used is less for a particular utility service, the GHG emission is also less. For example, a LED lamp consumes one fifth power than a filament lamp for the same lumen. When running in part load conditions the boiler efficiency falls. So, more input energy is to be supplied for generating 1 unit of electricity. More energy use from fossil fuel based power plants means more fuel will be combusted leading to more emission of GHG. Thus judicious use of energy with proper planning lowers the GHG emission. The renewable source of energy like solar, biomass, wind etc emits no/negligible GHG gases during its operation. However, life cycle GHG emission should be considerable as it may be due to the emission during manufacturing, installation and final disposal of the system. For renewable energy systems, the initial installation cost is high. The cost rises with the capacity increase. By energy management, the consumption of energy is reduced for the same utility service. Though the initial cost may be higher, renewable energy systems can be used with reduced carbon emission. Economics of the system will however depend on several factors including subsidy as a policy. Even if the overall energy efficiency of a fossil fuel based plant can be improved, carbon emission will also be reduced. Presently the main research challenge is to reduce the initial cost of renewable energy systems.

LCA Approach Regarding GHG Emission by Renewable

GHG emission from a renewable energy system may be assessed during operation. However, more relevant and accurate assessment of it will be throughout its life cycle, i.e., ‘cradle to grave’ means for the entire life period starting from manufacturing/ installation to final disposal of the system/plant. Life cycle assessment is a tool for the environmental impact assessment of any system based on the ISO 14040 and ISO 14044 methods (ISO, 2019). The life cycle assessment (LCA) methods include all the emissions of the system from cradle to grave. The various steps of the LCA are shown in Fig. 6. In life cycle assessment, at first the goal of the assessment has to be decided. Then the inventory analysis is done i.e., the source of materials needed to form that particular material has to be decided. The GHG emission and other environmental impacts are then assessed and analyzed. The life cycle emission potential of some renewable energy sources is given in Table 2 (Ray *et al.*, 2018). The GHG emission may take place during the production phase of the renewable energy equipment as well as the operation phase of the renewable energy gadgets and the disposal phase too. This process is shown in Fig. 6. In the renewable energy systems, the GHG emission in the production phase of the gadgets is due to the energy involved in mining the materials needed etc., for the fabrication of the devices. In the fabrication of photovoltaic panels, silicon is needed. Huge energy is needed to convert metallurgical grade silicon to solar grade silicon. At the same time the disposal of modules along with iron frames and all have a carbon loading effect on the environment. In case of the solar photovoltaic panels huge energy is needed to convert the metallurgical grade silicon to the solar grade silicon in an arc furnace. The sources of CO₂ emission at different stages of renewable electricity generation is shown in Fig. 7. In the perspective planning of choosing the energy options, the LCA approach is an important one. The Life Cycle approach gives the total scenario of the GHG emission from fabrication to utility and disposal. The renewable energy devices emit almost no GHG during its operation. But it emits some or more during the fabrication process. So in assessment of GHG emission for renewable electricity generation, life cycle assessment is more rational and accurate.

Fig. 6 Steps of life cycle assessment.

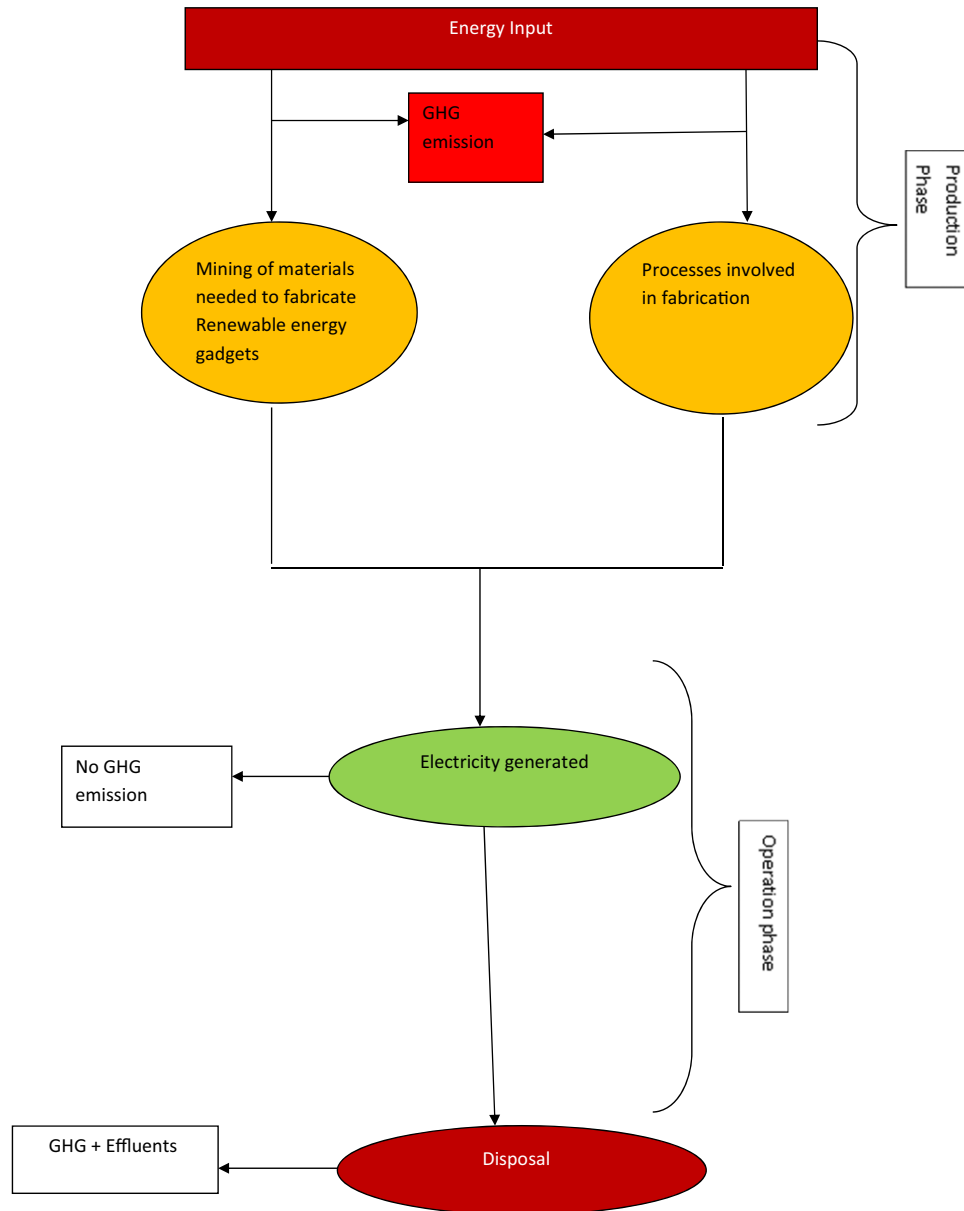

Fig. 7 Sources of GHG emission in life cycle of renewable electricity generation.

Conclusion

Fossil fuels have been dominating over centuries for generation of electricity. These fuels were economic and suitable technology for these fuels is matured over centuries. However, fossil fuel based electricity generation caused increased concentration of CO₂ in the earth's atmosphere. It being a GHG, the average temperature of the earth increased leading to the problem of the climate change. It is the greatest threat for survival of life on earth. As the effect of GHG emission is global though sources may be local, policies are to be decided globally though measures are to be adopted both locally and globally through international agreement. Several international agreements were signed and measures adopted internationally to fight this climate change. GHG emission due to electricity generation from fossil fuels is a serious concern globally. As renewable electricity generation generally emits no net CO₂, replacing fossil fuels by renewables for electricity generation may help reduction of GHG emission. As complete replacement of fossil fuels for electricity generation is not feasible due to several reasons, phasing it out over some period is an international mission. However, depending on available natural resources, different countries have varied constraints for this mission. Also, consideration of the CO₂ emission during operation only may not be the right method of concluding about the GHG emission due to electricity generation. The life cycle GHG emission should be estimated for the environmental impact due to CO₂ emission. It is noted that the life cycle GHG emission of the renewable electricity plants is much less than that of the fossil

fuel based power plants. Thus more use of renewable power generally reduces GHG emission. But the GHG emission by the renewable based power plants is not zero if the LCA methodology is applied. So, while considering the environmental impact of a system the LCA methodology must be applied to get a total estimation during entire life time of the operation of the plant or device. So, switching over to renewable power may be a better sustainable option if suitable economic technology can be developed to cater the electricity demand as a whole.

Renewable Jet-Fuel (RJF): Mitigation of Aviation-Related GHG Emission

Rajat Chakraborty and Ritika Samanta, Jadavpur University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Jet fuel (JF) also known as aviation turbine fuel is traditionally of two types viz. kerosene type and naphtha type. Kerosene based JF is a combination of several hydrocarbons having carbon range from 8 to 16 and Naphtha based JF having carbon range from 5 to 15. Over the years, the naphtha based JF has gradually been replaced by kerosene based JF.

With the growing population the demand for JF has also increased thereby increasing the utilization of crude oil and resulting in the depletion of natural resources. According to the US energy information administration, the supply of kerosene type JF has remarkably increased from 53,263 thousand barrels in March 2018 to 57,548 thousand barrels in August 2018. JF has market of 22-billion gallon per year in US and 80 billion gallon per year in the whole world (EIA International Energy Statistics, 2010). The consumption and price of JF have also been projected to increase by 40% by 2040 (Radich, 2015). The International Civil Aviation Organization (ICAO) predicted that there would be an augmentation in JF consumption in commercial flights from 140 million tons to 850 million tons over the years 2010–2050. Corresponding to the increase in JF consumption, an estimated six fold increments (i.e., from 442 million tons to 2686 million tons) in GHG emissions would occur during 2010–2050.

Notably, the emission of GHGs due to combustion of petroleum derived JF leads to environmental pollution and is also responsible for ozone layer depletion resulting in global warming and adverse climatic changes. The CO₂ emission from aviation industry globally has been projected by Business-as-usual (BAU) to be 3.1% every year, thereby causing 300% increase in emission by 2050 (IEA, 2008). It has also been set as a goal by the International Civil Aviation organization to accomplish carbon-neutral growth of aviation fuel by 2020 (International Air Transport Association press release, 2013).

The European Union (EU) has targeted 40% reduction in GHG emission by 2030 in comparison with that in 1990. Moreover, the bio-jet fuels (bio-JF) developed should emit 60% less GHGs than petroleum derived JF.

Renewable Jet Fuel (RJF)

RJF is the term used for JF being developed from different renewable feedstocks and which can be blended with petroleum JF at definite proportions to run jet engines. Development of RJF is being carried out to have a greener environment and sustainable fuel source. It is very essential to maintain the standard specifications prescribed by ASTM while formulating RJF viz. viscosity, pour point, calorific value etc. Due to JF's exposure to different temperatures like very low temperature at high altitude and in winter season or hot temperatures in summer or humid areas; it is essential to maintain the viscosity and pour point of the RJF otherwise it will be difficult for the aviation fuel to maintain its fluidity. A term "drop in" is commonly used for RJF in aviation industry which means a blend of 50% of RJF can be mixed with commercial JF according to ASTM7566 standards. The property of kerosene based JF (Jet A-1) according to ASTM standard is given in Table 1 (Abhari et al., 2010).

Production of Renewable Jet Fuel (RJF)

Initially the focus was on production of RJF from coal, natural gas, biomass which also included municipal solid waste, lignocellulosic agricultural and forest wastes using Fischer–Tropsch (FT) synthesis method. The coal derived RJF was referred

Table 1 ASTM specifications of conventional Jet Fuel (JF)

Properties	ASTM D-1655 Jet A-1
Flash point	38 min°C
Distillation EP	300 max°C
Viscosity @ – 20°C	8 max cSt
Freezing point	– 47 max°C
Density	0.775–0.840 g/ml
Heat of combustion	42.8 min MJ/kg
Smoke point	25 min Mm
Sulfur	3000 max ppm
Hydrogen	None mass %
Carbon (Saybolt)	None

to as “iso-paraffinic kerosene” (IPK) and was developed by Sasol in South Africa. “Synthetic-paraffinic kerosene” (SPK) derived from FT was employed for blending in military flights early in 2008 and in commercial flights in 2009. Another method for production of RJF being presently widely studied is hydroprocessed renewable jet (HRJ) in which RJF is produced from plant sources viz. jatropha oil, palm oil, rapeseed oil, salicornia oil, camelina, algae and also from animal fat e.g., rendered tallow. The RJFs produced from hydroprocessing of vegetable oil and animal fat have been given the name bio-SPK and “green jet”. RJF produced from lignocellulosic feedstock viz. switch grass, corn stover, short rotation woody crops etc., are also categorized as bio-SPK (Corporan *et al.*, 2011). Hydroprocessing renders hydroprocessed esters and fatty acids (HEFA) that may be deployed as RJF through processing of soybean and depolymerized cellulosic jet fuel (HDCJF). Corn stover, fermented sugars (HFS) besides RJF can also be produced from sugarcane and corn grain processing and hydrothermal liquefaction (HL). One more method for production of RJF is aqueous phase processing (APP). APP is used generally for conversion of woody biomass and alcohol to RJF in which sugar is first converted to ethanol which is subsequently converted to RJF. The U.S. Federal Aviation Administration has given approval to RJF developed from technologies viz. Alcohol to Jet SPK, HFS, HEFA, FT and FT synthesis with aromatics.

Recently, algae have achieved importance as feedstock for production of RJF, firstly, because it is possible to cultivate algae in nonarable land which minimizes the competition with agricultural land. Moreover, the productivity of algae per acre is high, its cultivation can utilize waste water and it has the potential to recycle carbon from industrial emissions. Importantly, it has demonstrated the ability to produce biofuels and valuable co-products.

In FT process the synthesis gas (syngas) is converted to paraffinic hydrocarbons which are further refined through processes like cracking, isomerization and fractionation to produce liquid fuel (Corporan *et al.*, 2007). The use of iron or cobalt supported chemical catalyst in FT process have also been carried out to meet the temperature and time requirements and thereby reducing energy involvement (Baliban *et al.*, 2013). As heteroatoms and aromatics are present in fewer amounts in this liquid fuel, it has been used as a green blend with conventional JF. This blend is termed as “semisynthetic” fuel.

Although the ‘semisynthetic’ fuel showed improved thermal oxidative stability and favorable emission properties; nonetheless, could not fulfill other specifications viz. density, lubrication property etc. The gas chromatogram of the synthetic JF and conventional JF (Corporan *et al.*, 2007) depicted that the synthetic/renewable JF contains less amount of aromatic compounds than conventional JF. With 50% blend of the synthetic JF with conventional JF, the aromatic content could be beneficially reduced to only 9.25 vol% (Lobo *et al.*, 2011).

Another technology which has gained significant importance is fermentation of suitable biomass feedstock. In this case, monomeric forms of sugars are converted to certain molecules using microorganisms e.g., yeast which are responsible for degradation of cellulosic feedstock which are further chemically upgraded to RJF.

Yet another method of production of RJF is ‘Ethanol to Jet’. Corn grain and corn stover are the two different feedstocks which have been used to produce ethanol and finally converted to RJF (Tao *et al.*, 2017). Ethanol can be derived from feedstock either through thermochemical route such as catalytic hydration of ethylene or through biological route which includes employment of enzymes and microorganisms responsible for fermentation. Companies like Byogy in Bryan Texas in U.S. are deriving ethanol biologically from the feedstock followed by conversion to RJF catalytically. During this conversion process the ethanol is dehydrated to ethylene which is oligomerized and the products are separated by distillation and then hydrotreating is carried out. It is necessary that the RJF being produced from ethanol meets the standard specifications for JF. Therefore, the first step dehydration is carried out to remove oxygen present in ethanol. After that catalytic dehydration of ethanol is carried out to form ethylene. The second important step is the formation of α -olefins. Through catalytic oligomerization process, ethylene is converted into linear and branched olefins. Depending on the operating conditions and the catalyst used, α -olefins produced ranges from C_4 to C_{32} hydrocarbons. Dimerization is also sometimes carried out to form a dimer of lighter hydrocarbons like C_8 to C_{16} olefins. Dimerization and oligomerization processes are carried out in a single reactor. Subsequently, the olefins are hydrogenated to form paraffins which are used as RJF. Green diesel and gasoline are also produced as co-products from biomass feedstocks viz. corn grain and corn stover.

Commercialization of RJF

RJF is already being used in commercial flights. Virgin Atlantic on 24th February 2008 used a blend of fatty acid methyl ester derived RJF with kerosene in the ratio of 20:80 to run B747-400 engine between London and Amsterdam. United Airlines on 11th March 2016 were the first to regularize the use of RJF as 30% blend with conventional Jet A1/8 fuel for running commercial flights from Los Angeles International Airport. The RJF was produced from non-edible feedstocks viz. agricultural wastes and vegetable oils. According to the International Air Transport Association (IATA), the United Airlines has planned to utilize RJF from 2019 for the next ten years targeting an anticipated consumption of 270,000 tons per year. It is being expected that there will be a 50% reduction in CO_2 emission by 2020 in comparison with 2005. Honeywell UOP utilized grant of U.S. Defense Advanced Research Projects Agency (DARPA) to develop technology for production of green JF. Algae, camelina etc., were utilized as feedstock for production of green JF. More than 1 million gallons of RJF has been produced by Honeywell for usage by U.S. military and commercial flights for mitigation of GHG emission and carbon footprint.

Indian standard RJF (17081:2019) consists of synthesized hydrocarbons developed from different feedstocks e.g., non-edible vegetable oil and tree borne oil. Indian Air Force has indigenously developed RJF that has been given trials and has eventually been approved by Centre for Military Airworthiness and Certification (CEMILAC) for utilization as a green blend with conventional JF. Bureau of Indian Standards (BIS) has worked in collaboration with Indian Air Force to produce RJF and use it as Aviation turbine fuel (ATF). According to 'Business As Usual', it is anticipated that 1/5th of the present GHG emission would be reduced due to the use of RJF as a green blending component with conventional JF.

RJF has been utilized by European countries over the recent years for both civil and defense aviation transport sector. The commercial production of drop-in biofuels has been projected to attain approximately two million tons by 2020 in coordination with companies viz. Biomass Technology Group, Neste Oil and UOP. In concurrence with European Union analysis, there would be a possible 95% life-cycle GHG reduction through employment of RJF as compared to conventional JF.

The global increase in demand of RJF has necessitated enhanced agricultural activities for cultivation of different non-edible feedstocks for RJF production. This would further improve employment opportunities and rural economy encompassing all stake holders.

Effects of RJF on Aviation Emission

The combustion of RJF in aircraft engine has profound effect on air-environment through mitigation of GHG emission. The jet engine exhaust components have different lifetime, viz. water vapor (9 days); CO₂ (approximately 20% for thousands of years) and NO_x (about 114 years). The longer lifetime of components like CO₂ results in the accumulation of these components in the earth's atmosphere. They are responsible for reducing the solar radiations returning to the atmosphere which in turn increase the reflection of solar radiations from the atmosphere. This eventually results in the increase in temperature of Earth's surface which is commonly referred to as 'global warming'. Individual components affect the climate differently; e.g., accumulation of NO_x components is responsible for the depletion of ozone layer. It has been found that 10% depletion in ozone layer can lead to 45% penetration of harmful UV rays to the earth's atmosphere, thereby, causing serious health issues like skin cancer. Other components like SO_x also accumulate in the atmosphere and when reacts with water form acid rain. Smog formation also results due to emission of non-methane hydrocarbons (NMHC). PM (Particulate Matter) emission and its reaction with water results in condensation and thereby forming contrails which contribute towards global warming; although their life expectancy in the atmosphere is short (Janic, 2018).

The PM emission of JF has been observed to be $2.25 \times 10^8 \pm 5\%$ particles cm⁻³ (Corporan *et al.*, 2007). It has been found that with the increase in the percentage of blend of RJF with conventional JF reduction of PM emission occurs up to approximately 97.5%–99.9% (Janic, 2018). The blend of RJF with conventional JF results in the release of smaller size PM and the smaller size make PM easily oxidizable. This is due to the presence of fewer amounts of aromatic compounds in RJF in comparison with conventional JF. The formation of soot nuclei also becomes less because of meager content of aromatics in RJF. It has also been revealed that RJF comprises of normal and branched aliphatic compounds which are less hazardous in terms of soot formation. Evidently, soot formation is unacceptable with respect to environment safety. Moreover, the RJF has high hydrogen (H) to carbon (C) (H-C) content which also helps in soot reduction. It has also been showed that there is a relation between the aromatic content and hydrogen content of fuel. Less than 5% polycyclic aromatics exhibit good correlations with H-C content and reduce soot formation. However, it's just the opposite with polycyclic content more than 5%.

Further, the sulfur content of RJF has also been found to be low as compared to conventional JF and therefore it helps in reducing particle formation by reducing the nucleation mode. It has been demonstrated that the oxidized sulfur compounds do not interfere in the PM formation and emission.

Besides, a strong relation has been observed in between the mean particle diameter and the concentration of RJF in RJF blended JF. The increase in concentration of RJF reduces the mean particle diameter from 28 nm to 17 nm thereby reducing the formation of soot nuclei. This ultimately reduces the availability of nascent particles for coagulation and facilitates reduction in PM emission.

Smoke number (SN) is another important fuel property which comes into consideration while discussing emission. SN is basically a parameter which reflects soot formation. Soot formation causes blackening of the smoke filter which is responsible for reflectance. In case of blend with RJF, as the soot formation is less there is a considerable decrease in SN. Moreover, SN is also associated with mean particle diameter. As the nanometer sized particle decreases in diameter with the increase in blend of RJF with conventional JF, SN decreases further. SN can therefore be said to have relation with PM emission and particle size decrement.

In case of gaseous emissions, NO_x emission decreases by approximately 11%–22% (Janic, 2018) after blending RJF with conventional JF. A slight decrease in CO₂ emission (approximately 2%) (Janic, 2018) was observed due to the presence of higher hydrogen to carbon (C-H) content in RJF. As the RJF is usually sulfur free, a considerable reduction in SO_x emission can be possible. Further, NMHC also reduces by approximately 18%–25% (Janic, 2018).

It has also been observed that the emission of components is dependent upon the feedstock chosen along with the location from where the feedstock is procured viz. rapeseed collected from different places of U.S. showed different NO_x emission. Although rapeseed has been found to be a better feedstock for RJF production than camelina, *Jatropha curcus* and soybean because of 40%–44% of oil content; however, the NO_x emission increases on usage of rapeseed as feedstock when overall process is considered starting from cultivation to utilization of rapeseed as feedstock. This is due to the fact that during cultivation of rapeseed, fertilizers are being used which contain N and are therefore harmful for the environment (Ukaew *et al.*, 2014).

The technology adopted for production of RJF also affects the GHG emission profiles. With application of fermentation technology on sugarcane, corn grain and switch grass the GHG emission rates could be reduced significantly as compared to conventional chemical conversion technologies (Staples *et al.*, 2014).

Life Cycle Analyses of GHG Pertaining to RJF

The life cycle of GHG emission of RJF is usually described using a term “Well to wake”. This term has been used to study both CO₂ and non-CO₂ combustion effects. It is expressed in the unit of energy. As per previous reports, 73.2 g CO₂/MJ is emitted when combustion of conventional JF occurs whereas the combustion of RJF emits 70.4 g CO₂/MJ (Stratton *et al.*, 2011). Notably, It has been observed that when RJF is produced from cellulosic biomass through APP technique, the ‘Well to wake’ GHG emission varies from 31.6 to 104.5 g CO₂e per MJ (Olcay *et al.*, 2018). Importantly, in case of application of fermentation technology for production of RJF from sugarcane, switch grass and corn grain, the ‘Well to wake’ GHG emission was found to vary from – 27.0 to 19.7, 11.7–89.8 and 47.5–117.5 g CO₂e per MJ respectively in comparison with 90.0 g CO₂e per MJ from conventional JF (Staples *et al.*, 2014). Evidently, the RJF results in much less GHG emission relative to conventional JF; and thus, facilitates mitigation of global climate change.

Generally 100 years is considered as the time span for analyses of impact of GHG on climate considering mainly those components which have longer lifetime in the atmosphere. 500 year time span is also considered in some cases. It has been found that atmospheric cooling occurs when there is reduction in ambient NO_x and soot over a time span of 100 and 500 years. This ultimately leads to reduced global warming. There has also been reduction of sulfur components which will lead to reduced global warming.

The life cycle analyses of the RJF utilized as blend with conventional JF, encompasses the impact of various steps on emission, viz. the cultivation of the feedstock, its transportation, processing, conversion to RJF and utilization as RJF (Bailis and Baka, 2010). One such well known feedstock is *Jatropha curcus*. The first stage is the acquisition of land and its preparation for *Jatropha curcus* cultivation. This step includes tilling, sowing, cropping, and seed harvest. During this step, proper irrigation is required which is also responsible for GHG emission. Further, limestone (CaCO₃) is also mixed with soil in some countries (e.g., Brazil), where the acidity of soil is high. This limestone when comes in contact with water forms solution of bicarbonates; and eventually results in the emission of CO₂ and water. Next component is the use of fertilizers to increase the yield of *Jatropha* seeds. The most commonly used fertilizer viz. urea breaks down and results in the emission of N₂O and CO₂; thus further contributing towards increment in GHGs emission.

The second stage is the transportation of the cultivated *Jatropha* seeds to the point where oil will be processed and converted to RJF. For transportation, vehicles are used which involve burning of fuel and therefore the second stage also adds to the emission of GHGs.

Fig. 1 Life cycle GHG emission concerning RJF derived from sugarcane.

The third stage is the production of RJF from the processed oil. In this step hydrogen is being utilized to get bio-SPK from refined Jatrophia seed oil. In this step also additional emission occurs which contributes towards global warming.

The fourth stage is the transportation of RJF from the refinery to the aircraft for its utilization as a green fuel blend with conventional JF. In this step also as vehicles are being used for transportation of RJF, the combustion of fuel in the vehicle will also lead to further emission of GHGs.

The final stage of life cycle analyses includes the blending of RJF with conventional JF and its utilization as liquid fuel in operating aircraft engine rendering additional emission of GHGs. Thus, the overall emission of GHGs would include the emissions of GHGs from all the stages.

Another important feedstock for production of RJF is sugarcane. Sugarcane is first converted into a compound namely farnesene through fermentation carried out using yeast. In the fermentation broth this compound is available as a separate phase as the top layer which facilitates its recovery. Farnesene is consequently carried to hydrogenation plant where it is catalytically hydrogenated to a compound referred to as 'farnesane' which acts as RJF and used as a green blend with conventional JF.

In the preceding process, the net GHG emission in g CO₂e/MJ would include all the emissions occurring starting from cultivation of sugarcane, its milling, syrup production, conversion of syrup to farnesene and finally to farnesane. The GHG emission is shown in Fig. 1 for production of RJF when sugarcane is deployed as feedstock. From Fig. 1, it is evident that maximum GHG emission (CO₂e) occurs during sugarcane production and land use change. Notably, it becomes negative when electricity and yeast are taken into account concerning GHG emission. Other factors which contribute towards GHG emission are also exhibited in the figure along with corresponding percentage of contribution (Moreira *et al.*, 2014).

It should be emphasized that, accounting the emission of GHGs in all the stages of RJF production and utilization would facilitate prediction of the life cycle analyses of any feedstock as illustrated in Fig. 2. The data of GHG emission corresponding to each step in life cycle analyses can be utilized for the development of sustainable technology for RJF production and end use.

A comparison of the GHG emission in g CO₂e/ MJ occurring due to several factors considered in the life cycle analyses has been exhibited in Fig. 3 for different feedstocks. From Fig. 3, it is evident that during utilization of fertilizers and chemicals for production of feedstocks, their transportation and their conversion into RJF using catalyst the GHG emission are relatively higher whereas in case of consideration of land carbon net emission, the GHG emission values obtained were negative.

Fig. 2 Life cycle analyses steps for net GHG emission for any feedstock.

Fig. 3 Comparison of GHG emission in g CO₂e/MJ RJF for different feedstocks.

Conclusions

This study emphasized on the mitigation of GHGs emission by employing RJF as a blending stock for conventional JF. It is apparent that the increasing population is leading to an augmented demand of JF. The more the utilization of JF the more will be depletion of our natural fossil fuels. Further, the burning of JF also leads to substantial emission of GHGs which are responsible for ozone layer depletion, global warming and eventual environmental pollution. This has led to the necessity for production of cleaner JF i.e., greener alternative RJF. At present, RJF is being commercially produced from various feedstocks like jatropha, sugarcane, algae and other lignocellulosic feedstocks through different processing technologies like Fischer-tropsch synthesis, hydroprocessing, aqueous phase processing, alcohol to jet conversion and fermentation technology. Commercialization of RJF is in progress globally through different public and private sector stakeholders. The public and private enterprises produce RJF employing proprietary technologies utilizing predominantly non-edible feedstocks e.g., tree borne oil, algae, camelina etc. The RJF should conform to specified standards and obtain necessary clearances from standard aviation regulatory authorities for employment as a green blending stock with conventional JF in military aircrafts and civilian flights for air transport.

From the present study, it can be concluded that RJF is efficient in mitigating GHGs emission and higher blending percentage of RJF with conventional JF can render further reduction of GHG emission in air transport. At present maximum 50% RJF blended with conventional JF is utilized to run aircraft engines. It is evident that the GHG emission of RJF produced from different feedstock is different. The net GHG emission combines all the emissions occurring due to cultivation of the feedstock, its processing, and transportation to refinery, conversion into RJF, blending with JF and utilization to run aircraft engine. This concludes that selection of feed stock and all processing steps are one vital for sustainable RJF production. It should be taken care of that the feedstock selected does not compete with food products for agricultural land for its cultivation. Moreover, waste management is also a vital issue in terms of land acquisition and overall environmental pollution. There is utmost need for development of sustainable technology to efficiently utilize all types of waste viz. solid waste, municipal waste, agro-waste, food industry waste etc., to produce RJF through energy-efficient and inexpensive pathway. RJF can also be produced from bio resources e.g., algae which can also be efficiently cultivated. Further, the increasing demand of RJF would lead to a boost in requirement of the feedstocks for RJF production. The increment in demand of non-edible plant based feedstocks would eventually lead to an enhanced growth in agricultural activities. Concurrently, new employment generation would facilitate enhanced economic growth.

The processing technologies currently utilized for production of RJF are energy intensive and makes the RJF costly. Therefore it has not become possible to commercialize it completely. The production process of RJF is still undergoing pilot scale development to achieve superior sustainability. There is an utmost need for the development of processing technology for formulation of RJF from lignocellulosic feedstock to make it more cost-effective. Moreover, RJF produced should be such that it meets the specified fuel standards as per ASTM or EU. It should have the ability to be blended with conventional JF at a percentage more than 50%. Importance should be given to reduce PM emission, aromatic compound formation, soot formation, release of harmful gaseous compounds viz. SOx and NOx, C-H content so as to effectively mitigate the net GHG emission reduction and achieve the target of carbon-neutral growth. Mitigation of GHGs could be possible through proper selection of feedstock and application of cost-efficient technology for conversion of the selected feed stock to RJF to have a greener, cleaner and healthier climate.

Introduction

Global warming and climate change have emerged as unavoidable components of any discourse related to growth in economic activities. Greenhouse gases (GHGs) that are at the heart of the concerns, absorb a part of solar energy that comes to the earth and radiates it back as heat. Increased concentration of these gases implies an increase in the amount of infrared radiation (heat energy) trapped in the atmosphere. This trapped heat energy in turn leads to an increase in the global mean temperature. While this was known to the scientific community since nineteenth century, there is augmented concern with regard to the same as it was realized that the anthropogenic emissions of GHGs can go beyond natural assimilative capacity and interfere with the bio-physical system on earth. Although the exact one to one correspondence between increase in GHG concentration in the atmosphere and increase in global mean temperature is yet to be established, several studies indicated likelihoods of exceeding a certain degree of temperature for a given level of stabilization of these gases. The 'hockey stick' plot of temperature rise that shows drastic increase in global mean temperature since the beginning of the 20th century following a flat pattern, by [Mann et al. \(1999\)](#) is now considered to be an evidence of global warming beyond doubt. According to the Fifth Assessment Report of Intergovernmental Panel on Climate Change ([IPCC, 2014](#)), under baseline scenario, without additional efforts to mitigate GHG emissions, global mean surface temperature can increase between 3.7 and 4.8°C in 2100 as compared to the pre-industrial level. A large portion of this emission is anthropogenic in nature and caused by combustion of fossil fuel to produce power and other economic goods to meet the growing consumer demand with population growth. Besides, land use change for e.g., clearing of forest reduces carbon sequestration capacity and contributes to the increase in GHG concentration in the atmosphere. Since the major cause of emission is anthropogenic, a coordinated human effort towards mitigation is the key to the solution.

Anthropogenic GHG induced climate change can be seen as a case of transboundary pollution leading to transnational externalities. So, the debate and dilemma over the questions of 'efficiency' of mitigation and 'equity' in burden sharing are expected to continue in a fragmented and unequal world. Economic efficiency in emission mitigation relates to minimization of abatement cost at the margin. Given the long lifetimes of the GHGs in the atmosphere, the efficiency also needs to be inter-temporal in nature. However, economic efficiency is a necessary but not the sufficient condition for sustainable development. It further requires achieving intra- as well as inter-generational equity and therefore raises a plethora of questions such as 'who will mitigate?', 'what should be the scale of mitigation?', 'during what time period?', 'who will pay for it?' etc. All these questions geared to seeking a strategy towards governing transboundary pollution and internalization of transnational externalities in a politically fragmented world, especially in the absence of a supranational government. Needless to mention the challenge is complex. The scope of Economics as a discipline has significantly expanded to deal with such complex questions of inter-temporal efficiency and equity related to emission mitigation. The issue is addressed based on the concepts of negative transnational externality created by emission, its impact on global commons, global public good characteristic of benefits from emission mitigation and the related free rider problem.

The current article addresses two issues: First, it introduces the readers to the fundamental argument that frames the concepts of economics of climate change mitigation. Second, based on empirical examples, it explains the complexity of solutions towards mitigation compared to standard economic problems. The rest of the article is arranged in the following manner: Section "GHGs Emission and Mitigation: Using the Lens of Economics" gives an overview of the basic concept of 'good' and 'bad' in economics, why market fails as an institution to govern a 'bad' creating 'negative externality' and how government can intervene to internalize the externality. It also discusses the additional challenges created by a 'bad' that is global, since there is neither a market nor a global government to internalize the externalities. Section "From Kyoto to Paris" provides a brief note on the nature of international agreements evolved over time to address climate change mitigation under such circumstances. This is to provide a glimpse of the role of supra-national bodies to surrogate market mechanisms and/or to create a form of global governance to internalize the externality. Although mitigation goal is a global goal, in a politically fragmented world policy instruments are mostly designed and implemented by national governments. This leads to Section "Designing Tax for Multiple Greenhouse Gases" that shows optimal design of policy instruments requires careful consideration of several facts – including the fact that emission mitigation involves not only carbon dioxide (CO₂), but of a number of GHGs with different implications towards climate change. Section "Levelized Cost of Conserved Carbon" talks about the levelized cost of conserved carbon (LCCC) and what additional information does it capture beyond near term cost-benefit assessments. Finally, the debate of managing GHG emissions by looking at the production based approach vis-à-vis consumption based approach has been addressed by focusing on measurement of carbon footprints using an empirical example in Section "Measuring Carbon Footprint".

GHGs Emission and Mitigation: Using the Lens of Economics

Negative Externality and Public Good

Human activity induced GHG emissions can be conceptualized as 'negative externality' created by a 'bad'. The identification of 'externality' dates back to 1920 when A. C. Pigou (Pigou, 1920) wrote about the problem of a smoke emitting factory causing damage to nearby business/residents. Clearly, the production behavior (This is applicable also in case of consumption activities) of one entity (the factory) here affects the production and/or consumption behavior of other entities. Here the externality is said to be 'negative' since the effect is damaging. If we continue with the example of smoke emitting factory, the question is how to ensure that such emission does not go beyond an optimal level or more generally, how to govern a 'bad' creating negative externality at a local level. In traditional economics, market as an institution facilitates exchange of 'goods' and services with well-defined property rights through price mechanism. The interaction of demand and supply of 'goods' determine an agreeable price where demand equates supply, an exchange takes place and the market clears. An overproduction relative to demand pulls the price down while any underproduction pushes it up. Market mechanism that helps managing 'good' is missing in case of a 'bad' in absence of demand. The 'bad' remains un-priced in the absence of a market that would otherwise generate a negative price of such pollutants. Had there been a market for 'bad', the producer of such 'bad' would have been liable to pay the market determined price to the consumer i.e., the affected entity. Over production of 'bad' would have implied more payment by the producer to the consumer generating some kind of disincentive to produce 'bad' (here the polluter/emitter) beyond the optimal level. This, if remains unpaid by the producer of 'bad', drives the gap between the 'social cost' and 'private cost'. Think of the same smoke emitting factory. The out of the pocket cost that the producer has to bear will include payments to various fixed and variable factors of production such as wage payment to labors, payment for raw material and fuel, payment for services such as transportation etc. These costs constitute the 'private cost', the cost that the producer has to pay as a private entity. In order to arrive at a 'social cost' one has to add to it all kind of costs inflicted upon the society by the production activity, including the cost of emission and pollution caused by the production process. As long the producer doesn't internalize the externality the divergence between social and private cost remains.

In absence of market mechanism, government often intervenes and uses appropriate fiscal instruments to internalize the externality. In the context of local pollutants, they are often in line with Pigou's solution to internalize the externality through imposing a per unit tax (equal to the difference between the social marginal cost and the private marginal cost corresponding to the social optimal output) on output of the polluting firm. The government can also impose restrictions through command and control. By doing so the government recognizes the 'public good' character of mitigation of 'bad'. Here the concept of 'public good' needs further clarification. In economic literature, a commodity or service is categorized based on two attributes: consumption rivalry and excludability. A piece of cake that is purchased from the market is characterized by both excludability as well as consumption rivalry and is called a 'private good'. It is excludable because if one doesn't have a certain amount of money to buy it, he/she will be excluded from the consumption. The consumption rivalry arises from the fact that if one person consumes it, less will remain for any other person to consume. This is however not the case for a service such as street lights. Once the provision is made, nobody can be denied of the service. Also, one person's consumption doesn't affect other's share. Similarly, if the smoke emitting factory reduces the pollution the benefit of pollution reduction will be felt in the entire locality in a similar manner and hence has a 'public good' character.

The phenomenon of climate change is a special case of externality with layers of complexity. First, negative externality caused by GHGs is transboundary in nature- the effects of emission are not restricted within the geographical boundary of the emitting country (Hanley et al., 2006). GHG emitted by one production/consumption entity accumulates in the global atmosphere, irrespective of its source and creates negative externality such as increase in global mean temperature, climate change etc. in a global scale. What is unique about these gases is the uniformity of mixing i.e. they spread relatively evenly in the atmosphere around the globe. The impacts of accumulated GHGs are felt on global commons such as atmosphere, ocean, biodiversity reserve etc. and stands for a case of transnational externality. That is the reason why they are called 'global pollutant' in contrary to their local counterparts such as SO_x, NO_x, particulate matters etc. The uniformity of mixing and the impact over the globe makes the problem extremely complex. So far for local pollutants, although the market didn't exist, national governments could either take up a command-and-control policy to cap the emission or use fiscal instruments to generate optimal solution. But to manage GHG emission, neither market nor a supra-national government exists. Fiscal instruments of national governments are not capable of internalizing externality since decrease in welfare of one country may well be a result of actions propagated by some other country. As the impact of emission is transboundary, so is the impact of emission mitigation. This is simply because if country A undertakes some mitigation actions, the climate benefit or the safe-guard to global common will be available to the entire world. If the mean temperature stabilizes and climatic condition over the globe is improved due to emission mitigation, then no one can be denied to be a beneficiary of the same. Also, one person enjoying the benefit of climate change mitigation doesn't reduce the scope of it by anyone else. So, climate benefit derived from emission mitigation is 'non-excludable' and 'non-rival' at an international scale and is therefore a 'global public good'. This has a tendency to lead to a situation where no one is willing to pay for mitigation as everyone will assume that the others will pay while he/she can enjoy the benefit. The tendency of such 'free riding' is at the heart of market failure for anything with the public good characteristic. The problem becomes even more complex if intergenerational equity is brought into the picture. Since accumulation of GHG in atmosphere is likely to render adverse climatic consequences in

future, the main demand from emission mitigation should have come from them, which is again non-existent at present. Any discussion on this is however, beyond the scope of this paper.

Given such circumstances, efforts are extended in two directions: first to augment the role of international cooperation and establishment of supranational bodies such as United Nations Framework Convention on Climate Change (UNFCCC); second, to augment the application of policy instruments that may seem to be useful in addressing this complex problem. The frontier of economic research has also been expanded to address these issues in the context of climate change mitigation. In the sections we discuss such international negotiations as new global order to manage GHG emission.

From Kyoto to Paris

The role of international cooperation is often considered to be the key to climate change mitigation in absence of supra-national government in a politically fragmented world. Beginning in 1992 through the establishment of UNFCCC followed by Kyoto Protocol in 1997, the nature of international negotiation and cooperation with regard to climate change has experienced significant evolution. The Kyoto Protocol classified countries based on their historical emissions in terms of Annex I and non-Annex I countries. While Annex I i.e., the developed countries faced a target of emission reduction, though legally non-binding in nature, there was no such mitigation target for non-Annex I countries. The protocol, this way, recognized the equity issue of burden sharing by stating that the heavier burden was placed on the developed countries for the 'current high levels of greenhouse gas emissions in the atmosphere as a result of more than 150 years of industrial activity'. This was coined as the principle of 'common but differentiated responsibilities'. However, several efficiency factors including the perception about the impact of climate change, cost of emission reduction, domestic and international policies – all shaped the emission mitigation activity profile of countries (see "Relevant Websites section"). The dynamics however, changed significantly over the years as learning by doing is increasing. Several direct and indirect policies are getting implemented while countries are learning from past mitigation experiences. In order to bring more countries on board, to achieve the target mitigation in a least cost manner, the idea of 'common but differentiated responsibilities' was reformulated in terms of 'Intended Nationally Determined Contribution' to climate change mitigation. In 2016, the Paris Agreement intended to 'strengthen the global response to the threat of climate change, in the context of sustainable development' to restrict the increase in the global mean temperature to 1.5°C above pre-industrial levels.

Designing Tax for Multiple Greenhouse Gases

As a policy instrument for emission mitigation, global carbon tax is widely discussed and has also been tested in some parts of the world. However, while talking about emission mitigation one needs to be careful to take into account a group of GHGs and not CO₂ alone. It is a case of multiple pollutants, such as CO₂, Methane (CH₄), Nitrous oxide (N₂O), several Fluorocarbons (such as CFC11, CFC12, HFC23) etc. What is important is to note that the sources of such pollutants are significantly diverse. While fossil fuel burning and deforestation is the primary source of CO₂ emission; livestock, rice cultivation and manure management are major sources of Methane. Nitrous Oxide emission, on the other hand, mostly comes from the agricultural activities and the use of fertilizer. Even if the problem caused by over concentration of each of these gases is similar in nature, the degree of the effect is not identical. So, 'how many tons of CO₂ would lead to similar impact caused by a ton of CH₄?' is a question of immense importance to design efficient economic instruments such as emission tax. As soon the concern is to tax a group of pollutants, and not CO₂ alone, the issue of relative taxation becomes important (Michaelis, 1992). What should be the optimal tax on CH₄ relative to CO₂? To answer this question it is important to know two scientific characteristic of these gases: the capacity of absorption of the infrared radiation and its natural rate of degradation in the atmosphere or inversely, their atmospheric lifetime. The first one gives an idea about the amount of CO₂ equivalent to one unit of the other GHG in terms of its greenhouse impact and the second one provides information on how fast does the natural removal of the gas from the atmosphere take place. It is therefore important to have a knowledge of accurate values of these natural parameters to have a multiple pollutant tax policy in place. Higher the capacity of absorption of the infrared radiation and lower the rate of degradation (or longer the atmospheric lifetime), higher will be contribution of the gas to global warming. Michaelis (1992) in his paper "Global Warming: Effective Policies in the Case of Multiple Pollutants" developed a model to design optimal tax policy for multiple pollutants. This model has its own merits to solve for the efficient level of relative taxes for multiple GHGs in a simplified manner. The model also formulates the optimal time path for taxes on each of the gases from a dynamic optimization perspective. It shows that if the economic objective is to minimize the discounted flow of abatement costs (C) (i.e., the cost of mitigation) subject to the warming constraint (for example, not letting the mean surface temperature of the earth to go beyond 1.5°C over and above the pre-industrial level), then the problem of a central planner would be:

$$\begin{aligned} \text{Min } C &= \sum_{t=0}^T \sum_{i=1}^n C_i(v_i(t)) / (1+r)^t \\ \text{Subject to : } S(t) &\leq S^0 \\ \text{or, } (\Sigma)_i (\Sigma)_j \alpha_i (1 - q_i)^{T-t} e_i(t) &\leq S^0 \end{aligned} \quad (1)$$

Table 1 Global warming potential (100 year time horizon) and atmospheric lifetime (http://www.ghgprotocol.org/sites/default/files/ghgp/Global-Warming-Potential-Values%20%28Feb%2016%202016%29_1.pdf)

	1995 IPCC second assessment report	2001 IPCC third assessment report	2007 IPCC fourth assessment report	2014 IPCC fifth assessment report	Atmospheric lifetime
Carbon dioxide (CO ₂)	1	1	1	1	100
Methane (CH ₄)	21	23	25	28	12
Nitrous oxide (N ₂ O)	310	296	298	265	114
HFC 23	11,700	12,000	14,800	12,400	260

Where, $C_i(v_i(t))$ is the cost of the mitigation measure v_i (related to gas i) at period t and r is the social rate of discount. So, C gives the present value of the stream of abatement costs over time horizon T . The constraint implies that the stock of all GHGs measured in terms of their CO₂ equivalence $S(t)$ should not exceed the threshold S° . Two scaling parameters α_i , to capture the amount of CO₂ which is equivalent to one unit of GHG i.e., the warming potential in terms of its greenhouse impact and q_i to capture the natural rate of degradation are used to derive the equivalence. Solving the problem for two GHGs i and j gives the static optimum for each period as

$$\frac{C'_i[v_i(t)]}{C'_j[v_j(t)]} = \frac{\alpha_i}{\alpha_j} \left[\frac{1 - q_i}{1 - q_j} \right]^{T-t}$$

$$C'_i[v_i(t+1)] = \frac{1+r}{1-q_i} C'_i[v_i(t)] \quad (2)$$

This implies that the mitigation activities are to be combined in such a way that the ratio of marginal abatement costs of two GHGs should be equal to the ratio of their warming potentials adjusted for the rate of natural decay. The implications are similar in case of a decentralized planner. So, higher the global warming potential of a GHG, higher will be the relative tax and quicker it degrades the lower will be the relative tax rate. Michaelis calculated the paths of the tax rates based on α_i , q_i depicted in IPCC Report, 1990, taking social discount rate=4% for a twenty year time period. However, certain complexities exist in estimating these natural parameters. These values are estimated on the basis of scientific understanding and the precision of such estimation changes over time. While the most widely accepted definition and figures for the GWPs are presented by IPCC but the values are continuously being modified with increased precision of scientific modeling. As a result, no two Assessment Reports of the Panel could furnish the same value for warming potential of these GHGs. Table 1 gives a glimpse of changing reported GWP of three GHGs over time: Methane (CH₄), Nitrous Oxide (N₂O) and a fluorocarbon- HFC23.

In this article, an attempt has been made to see the effect of such changes in the values of natural parameters on the optimal tax path. The optimum tax paths are calculated based on Eq. (2). While the atmospheric lifetimes are assumed to be constant over time, (100, 12, 114 and 260 years for Carbon Dioxide, Methane, Nitrous oxide and HFC 23 respectively), GWP is varied based on IPCC reports. The rate of discount is assumed to be 4% and the time period considered is twenty, as assumed by Michaelis. Further, the tax on CO₂ in the first period is assumed to be unity.

The optimum tax paths for these pollutants are depicted in Fig. 1. CH₄ 1995, in the north east box in Fig. 1, shows the optimal tax path calculated for methane based on the warming potential reported in 1995. Other graphs have similar implications for other gases and other years. There are few important matters that need attention. First, if at the first period the tax on CO₂ is unity, then the relative tax on methane, nitrous oxide and HFC 23 should be approximately 7281 and 13,938 respectively (considering the global warming potential reported in 2014). Further, the optimal tax paths will be different if the warming potential is changed. This explains the gaps between the curves in each diagram calculated on the basis of different warming potentials. It also shows that in the short run, the divergence may not be significant (for initial periods tax rates being almost equal irrespective of the warming potential), but it increases over time. Therefore, it has significant implications towards long term decision making with regard to climate change mitigation. This also has serious policy implication as the sources are different for different GHGs implying different degrees of burden on different sectors. So, implementation of any tax for a reasonably longer period of time calculated on the basis of inaccurate GWP or atmospheric lifetime will distribute tax burdens on sectors in a sub-optimal way following the essence of the model. Any policy designed for very long run always has less flexibility to incorporate modified values of these parameters. This limitation has a very important role to play in deciding the length of a policy, especially in the global context. So, there is a need for constant reformulation of tax rates based on new parameters.

Levelized Cost of Conserved Carbon

The literature on climate change mitigation has been moving beyond usual cost benefit analysis as expected benefits of mitigation policies often ignores the irreversibility of climate change and related risks. This leads to cases where estimated cost exceeds the

Fig. 1 Optimum tax paths for Carbon Dioxide (CO₂), Methane (CH₄), Nitrous oxide (N₂O) and HFC 23.

estimated benefit in a shorter time frame. However, if one can see to the fact that the impacts of climate change are irreversible, the benefit derived from climate change mitigation seems to be extremely high though unquantifiable. The appropriate objective therefore, is not to implement a mitigation measure where benefit exceeds cost, but to choose the least cost mitigation option to achieve the target of climate stabilization (see “Relevant Websites section”). LCCC gives a good methodological base in this context. This section is based on a related study where the concept of LCCC was deployed to assess a range of energy efficiency measures implemented in a set of Indian industries (Fischedick *et al.*, 2014). The analyses of the cost of such energy efficiency measures and the resultant emission mitigation provide an opportunity to come up with the effective mitigation cost per unit of CO₂.

Assuming, annual emission reduction, annual operation & maintenance costs and annual benefits to be constant over the lifetime of the technological option, LCCC can be represented as:

$$LCCC = \frac{(CRF * \Delta I) + \Delta O \& M}{\Delta C} - \frac{\Delta B}{\Delta C} \quad (3)$$

Where,

$CRF = \left(\frac{i}{(1+i)^n - 1} + i \right)$, i is rate of interest and n is the lifetime of the option in years

ΔI is the investment to deploy the energy efficiency measure

$\Delta O \& M$ is annual operation and maintenance costs

ΔB is the annual benefits compared to a baseline for which no such measure is implemented (for example, avoided cost of energy, cost of avoided emission etc.)

ΔC is annual emission reduction.

To arrive at LCCC, data are required on the annualized investment cost of the measures, annual operation and maintenance cost of the measures and energy saved and/or emission avoided per year as compared to the no policy scenario. Bureau of Energy Efficiency (under Ministry of Power) in India publishes the investment cost of the energy efficiency measures adopted by the winners of the National Awards on Energy Conservations (One of the innovative voluntary schemes initiated by the Government of India, Ministry of Power, to promote energy efficiency and conservation is the Energy Conservation Awards to the industrial units) in different years. To compute the annualized investment cost the rate of interest has been assumed to be 8% per annum. The lifetime of the technology/measures are determined on the basis of expert consultations. Once the annualized investment cost is computed, the operation and maintenance cost is assumed to be equal to 10% of the annualized investment cost. The dataset also mentions the energy-saving potential of each of the measures in either of the two following ways (i) avoided energy cost per year in INR or (ii) avoided energy use per year in kWh. For some measures, both (i) and (ii) are mentioned in the dataset and based on that the cost incurred by the industrial units per kWh is calculated and it is found that on an average the value is close to INR 4.99 (USD 0.1) (1 USD = 45.67 INR; source: see “Relevant Websites section”). Using this conversion ratio the avoided energy use per year is obtained for the measures where only (i) is furnished in the dataset. Further, in India, an average of 0.94 Kilogram of CO₂ is emitted per kWh of electricity generation (Raghuvanshi *et al.*, 2006). Using this emission factor we also estimate how much CO₂ emission is mitigated when a particular amount of energy use is avoided through implementation of an energy efficiency measure.

A wide variety of energy efficiency measures implemented by Aluminium (26), Cement (42), Chemical (62), Integrated Steel Plant (ISP) (30), Pulp and Paper (46) and Textile (75) industries during the period 2007–2012 in India are considered. These measures have been implemented at varying costs. The technologies/measures are divided into six categories based on the cost per

Fig. 2 Energy efficiency measures taken and mitigation achieved by Indian industries under various cost (USD₂₀₁₀/tCO₂) categories.

ton of avoided CO₂ emission. It ranges from '0–20 USD per ton of avoided CO₂ emission' to 'more than 100 USD per ton of avoided CO₂ emission'. The distribution of the measures among the cost categories is represented in the left hand panel of Fig. 2. It shows that 87%, 73%, 47%, 46%, 58% and 78% of the measures adopted in the Integrated Steel Plants, Aluminium, Cement, Chemical, Pulp and Paper and Textile industries, respectively, fall under the least cost category '0–20 USD per ton of avoided CO₂ emission'. In fact 63% of all measures across industries fall under this category. To understand the mitigation potential of the measures under various cost categories, the distribution of total mitigation achieved over six cost categories (right hand panel of Fig. 2) is presented. It shows that those 63% under the cost category '0–20 USD per ton of avoided CO₂ emission' are associated with 93% of total avoided CO₂ emission. For Integrated Steel Plants, Aluminium, Cement, Chemical, Pulp and Paper and Textile industries 100%, 78%, 48%, 49%, 63% and 65%, respectively, of avoided CO₂ emission are associated with the least cost category. This shows that most of the energy efficiency measures and the related emission mitigation are associated with low per unit costs of avoided emission. However, some high cost options have also been implemented by some production units.

Eq. (3) also shows that LCCC will be negative when the benefit derived from the energy efficiency measures exceeds the cost of the same for each unit of avoided emission. Now the benefit can be derived from two sources: avoided energy cost and revenue derived from avoided emission in presence of a functional carbon market. Most of the measures under consideration, however, yield a negative value of LCCC even without consideration of any carbon price. This implies that the energy bills saved through implementation of these measures are high enough to offset the cost of the measures in this example. There are, however, few high cost measures (all of them falling under the cost category 'more than 100 USD per ton of avoided CO₂ emission') for which the LCCC is positive and the cost of the measure exceeds the benefit derived if only the avoided energy bill is considered. Next, we try to add the second component of benefit i.e., the revenue that can be derived out of the avoided emission in presence of a carbon market. The trend of volume weighted average price of CO₂ (USD/tCO₂) in the global carbon market (Fig. 3), shows that during 2007–2011, it peaked in 2008 to touch the value 30USD/tCO₂ (Bloomberg, 2012).

So even if the highest carbon price (30USD/tCO₂) is added as benefit derived from the energy efficiency measures through avoided emission, the positive sign of LCCC of these high cost measures remains unchanged. In other words, in our example 94% of avoided CO₂ emission achieved through 65% of measures is associated with a negative LCCC with carbon price greater than or equal to 30 USD/tCO₂. This leads the way towards a discussion how a low carbon price will fail to capture the social benefit derived from emission mitigation.

Measuring Carbon Footprint

Traditional economics conceptualizes consumer's equilibrium as the highest level of satisfaction that she can derive from the consumption of goods and services given the price and income constraint. This implies with an increase in population, leading to increase in the number of consumers and an increase in average income across world, demand for goods and services will grow, if the real prices do not go up significantly. However, if climate change is taken into consideration, income is not the only constraint, there are also global bio-physical constraints. GHG assimilation capacity of the atmosphere is one such example. Therefore, new indicators are emerging to see the implications of production and consumption to address such bio-physical constraints.

In addition to traditional economic performance indices, recent literature therefore suggests several alternative performance indicators to monitor resource use pattern in bio-physical terms (Chakraborty and Roy, 2013): Ecological Footprint (EF), Energy Footprint (EnF), Water Footprint (WF) and Carbon Footprint (CF). Among these four measures, the oldest is EF, introduced in the 1990s by William Rees

Fig. 3 Volume weighted average CO₂ price in global carbon market. Derived from Bloomberg, 2012. Bloomberg new energy finance. The future of energy 2012 results book. New York. Available at: <https://about.newenergyfinance.com/blog/bloomberg-new-energy-finance-2012-summit-results-book/>. (accessed 26.07.2018).

and Mathis Wackernagel (Rees and Wackernagel, 1994). It measures the use of available bio-productive space (in hectares) to the entity. EnF (in hectares), accounts for the bio-productive space needed as a 'sink' for assimilating the waste generated by human induced activities. WF is a measure of the volume of freshwater used at the place where the actual production and water use take place. It is normally expressed as green, blue and grey WFs: the green WF refers to the consumption of rainwater stored in the soil as soil moisture; the blue one refers to the evaporated surface and ground water and the grey WF refers to volume of freshwater required to assimilate the load of pollutants. Finally, the concept of CF originated from the concept of EF and came to be widely known since the year 2005 (Safire, 2008). It refers to the sum of GHG emissions caused by an organization, due to event or production and is expressed in terms of CO₂ equivalent. CF can be measured for a product or supply chain of a product; public or private institutions, such as universities; industry/business houses or companies including small and medium enterprises (SMEs), service agencies, data centres etc., or for a country or some parts of a country. While the concept of CF is relatively new, it has gained immense importance in the domain of climate change mitigation. This section discusses measurement of CF based on a related case-study in India.

Product Carbon Footprint (PCF) is one of the emerging environmental performance indicators that work as a part of larger contributory effort to expedite the move toward a low carbon economy. It estimates the extent to which products and activities of a business house along the supply chains contribute to carbon emissions. It is also useful to cater to the growing demand of the stakeholders for low-carbon products along with associated carbon information. It provides an opportunity for the businesses to identify the drivers behind emissions, scope to reduce emissions across the product life cycle leading to cost savings, supporting the development of future low-carbon products, and thereby contributing in emission mitigation. Direct and indirect emissions from three main sources are usually included for calculating the overall Carbon Footprint as per Life-Cycle Assessment (LCA) GHG Protocol Standard (WRI and WBCSD, 2008), namely: Scope 1 – only direct GHG emissions i.e., emissions that are owned or controlled by the entity, e.g. emission from own power generation (including back-up power generation), fuel used in the canteen of any institution, where kitchen is attached, emission resulting from the use of company/entity-owned vehicles etc., Scope 2 – indirect emissions occurring from consumption of purchased electricity or steam, and Scope 3 – all indirect emissions other than under Scope 2. Examples of indirect emissions under Scope 3 include emissions from distance traveled and fuel burnt for employees traveling for business purpose, transportation of input, output and disposal of wastes etc. (Rothberg, 2011).

The present case study is related to measurement of PCF of a ton of newsprint paper manufactured from wastepaper by a paper production unit in West Bengal, an eastern state in India and is reported from the work of Chakraborty (2015). The calculation is based on PAS 2050 method that includes GHG emissions from energy use, combustion processes, chemical reactions, refrigerant losses and other fugitive gases, operations, service provisions and delivery, land use change, livestock, other agricultural processes and wastes in the assessment (Plassmann et al., 2010). Capital goods are not taken into consideration in the PAS 2050; emissions related to human energy inputs, transport of consumers to and from shops, transport of employees to and from work are also excluded. In the present case study organizational boundaries encompasses both the operations over which the organization can exercise its control and also those like transportation of raw materials, wastes and finished goods. GHG emitted for producing a ton of paper measured in terms of kg CO₂e has been considered as the main operation in this case study. The product related GHG emissions have been classified under six stages or heads, taking into consideration the consumption of electricity, freshwater, wastewater and generation of wastes: pulping stage, paper making stage, finishing and conversion stage, steam generation, water treatment and distribution of finished products.

While activity data are collected through primary surveys, data on emission factors are obtained from secondary sources. The data collection process was as per PAS 2050 analysis requirements. For each activity PCF has been calculated based on the following equation:

$$\text{Activity (kg/litres/kWh/tkm etc.)} \times \text{emission factor (kg CO}_2\text{e per kg/litres/kWh/tkm)} \quad (4)$$

Emission figures obtained from each activity are then summed up to calculate total CF.

Results suggested that total emissions produced by the production unit for the year 2013–14 was 33,788,800 kg CO₂e for producing 18,000 tons of paper. PCF of a tone of paper was 1877.16 kg CO₂e. The breakdown of the unit's carbon footprint (in kg of CO₂e) shown under the various stages of production reveals that the largest source of emission for producing a tone of paper resulted from steam generation process, followed by paper making and then pulping. The remaining emission resulted from distribution of finished goods (occupying the fourth largest segment) and emission from finishing & conversion being the least

contributor. An analysis of percentage-wise contribution of production and distribution components towards greenhouse gas emissions (in kg CO₂e) per ton of paper production revealed that grid energy was on the top of the list followed by fuel (non – coking coal grade C&D) consumption and waste. Transportation of raw materials, wastes and finished goods, freshwater and wastewater were in the fourth, fifth and sixth position in the contribution league.

The study was useful to identify the emission hotspots of the industrial unit and to develop recommendations accordingly. From the calculation of the value and analysis of results of product carbon footprint it may be inferred that this footprint calculation results in communicating information on the environmental impacts to the business, its stakeholders and to the public at large. The results obtained by using this new performance footprint indicator, provide an assessment of the production unit's environmental impacts over time and in developing an assessment of sustainable limits for the product manufactured by the case study unit.

Summary

This article introduces readers to the fundamental concepts of economics that are used to address the issue of climate change mitigation. It discusses how GHG emission can be conceptualized as a 'bad' generating 'negative externality', that too transboundary in nature, and why market fails as an institution to govern a 'bad'. It also discusses why intervention by national governments in absence of a supra-national government is not able to internalize negative externalities created by GHG emission. However, international agreements evolved over time to address climate change mitigation in a politically fragmented world. The roles of such supra-national bodies to surrogate market mechanisms and/or to create a form of global governance to internalize the externality had been important. Designing instruments for emission mitigation is a challenge since there are several layers of complexities. This article demonstrates how optimal design of policy instruments requires careful consideration of several facts – including the fact that emission mitigation involves not only carbon dioxide (CO₂), but of a number of GHGs with different implications towards climate change. Emission mitigation involves cost. The LCCC method allows industries or other economic units to get a clear comparison of the cost of emission mitigation measures vis-à-vis their mitigation potential. Finally, it shows how in a bio-physically constrained system, new indicators related to carbon footprint can provide a useful measurement tool. Needless to mention that this article is not an exhaustive attempt to apply economic lens to GHG emissions issue but just a modest beginning.

Introduction

Emissions of phylogeny greenhouse gases changing Earth's climate and enforce substantial risks for current and future generation. To manage these climate hazards what are the strategies to be followed which are scientifically sound, economically strong, and ethically defensible. Seriously addressing temperature change due to climatic conditions suggests that cutting carbon emissions and, ultimately, reducing the carbon already within the atmosphere. There's no means around it. Another sort of involvement, however progressively gathering attention: Solar Geoengineering, which is a process where sun rays are reflected back to space and make earth's surface cool. For climate change it's not a permanent solution, and having a drawback of alarming environmental and political risks which are caused by its own, however, it's a tough price exploring (Wagner and Weitzman, 2018). The principle underlying solar geoengineering is easy enough: Brighter colors reflect more light. That's why houses in Mediterranean villages are usually painted white. Because of this situation scientists are concerned about the loss of polar ice, which have a sensible surface that reflects the incident solar radiation. Where open water will absorb sunlight and heat. In 1965 a suggestion was given to US president for solving the problem is solar geoengineering. First attempt has made to brighten ocean surface on a grand scale by using solar geoengineering.

As the research is shifted from oceans to the skies, the first important and widely discussed basic scheme is solar geoengineering which involves spreading small reflected particles within upper portion of the atmosphere. Answer to the question that solar geoengineering will work or not is given by the nature. Large volcanic eruption usually decreases the mean average global temperature. On 1991 in Philippines eruption of Mt. Pinatubo released almost 20 million tons of sulfur dioxide into the stratosphere. The global mean temperature in 1992 has decreased almost a degree Fahrenheit because of the eruption (Wagner and Weitzman, 2018).

But volcanic eruptions are generally large natural events, providing a rapid and temporary global cooling. Temperatures shortly return to previous levels. Solar geoengineering would need further careful and long-term approach. When we are doing practical problem and solving that problem it should start slowly and the effect could be considerable for long term. The scientists framed out a research hypothesis the basis of a proposal to decrease half of the increase in global average warming from a specific date onward. The situation is like that they are preparing up for after a decade a million tons of sulfate aerosol is to deliver in the stratosphere each year. We can't notice the impact of that work with our naked eye where 1% of solar radiation reflects back in to space (Wagner and Weitzman, 2018).

The burning of fossil fuels releases 25 Pg of CO₂ per year into the atmosphere, which is leading to global warming. It also emits 55 Tg Sulfate as SO₂ per year (Stern, 2005), in which half of this is converting into sub-micrometer size sulfate particles, the remainder being a dry deposit. Sulfate particles partially counter the concentration of greenhouse gases by backscattering solar radiation into space. Sulfate particle acts as cloud condensation nuclei and it also influences properties of the cloud likely micro-physical properties and optical properties which increase cloud albedo (Crutzen, 2006a,b).

There is a problem that we can't simply make such decision responsibly because we don't know enough about which material would be the safest and most effective when we use them. Sulfate aerosols used in most plans, largely because they are matching with the known effects which are observed in volcanic eruptions. But there is a problem with these aerosols they play a role in depleting stratospheric ozone. By some preliminary research points, calcium carbonate has a possible use as an alternative. Making the planet more reflective is not a replacement for cutting carbon-based pollution. Solar geoengineering is not a substitute for cutting emissions. It is at best a supplement (Wagner and Weitzman, 2018).

If we combine cutting of greenhouse-gas emissions and solar geoengineering then we can keep the temperatures of the planet under 1.5°C. Decreasing the emissions alone cannot bring the temperature down. As the emissions are stopped inertia of the climate and uncertain feedback such as loss of permafrost carbon, there will be a significant change but the world continues to warm for more than a century. Reducing the effect of heat-trapping greenhouse gases by reflecting a small fraction of sunlight back to the atmosphere is a process done by humans is called solar geoengineering. In a future large range of research efforts can yield quick progress because development in the technology of solar geoengineering would be a great exercise in the application of existing tools of aerosol science, atmospheric science, climate research, and applied aerospace engineering (Keith et al., 2017).

We cannot judge the results of solar geoengineering meaningfully without a scenario of implementation practically. It is now common to assess the balance between the risks and benefits of solar geoengineering effectively more scientific research is needed, here after it can be called solar radiation management (SRM). Any technology will have a set of technology-specific impacts for producing radiative, such as ozone loss arising from the introduction of aerosol particles in the stratosphere. A risk listed occur by SRM is ocean acidification, yet acidification depends almost solely on cumulative CO₂ emissions and is unaffected by SRM. If

Fig. 1 Impact on climate by the time with reduction in CO₂. Reproduced from MacMartin, D.G., Ricke, K.L., Keith, D.W., 2018. Solar geoengineering as part of an overall strategy for meeting the 1.5°C Paris target. *Philosophical Transactions of the Royal Society A: Mathematical, Physical and Engineering Sciences* 376, 20160454.

SRM is used as a substitute for emissions mitigation then ocean acidification is a risk of SRM but in this case, the risk derives from the increase in emissions not from SRM (Keith and MacMartin, 2015).

SRM scenario combines three elements: a specific method of altering solar forcing, an initial trajectory for SRM radiative forcing over time, and a plan for altering the trajectory based on new information. SRM scenario is chosen to meet the following criteria (Keith and MacMartin, 2015):

- (1) It is temporary in that the endpoint is zero SRM.
- (2) It is moderate in that it does not offset all of the global mean temperature change due to increased greenhouse gases.
- (3) It is responsive in that it explicitly recognizes that the amount of SRM will be adjusted in light of new information (Fig. 1).

As mentioned in previous discussion which is to decrease the atmospheric temperature there is agreement done in Paris which has a specific goal of holding the increase in the global average temperature to well below 2°C which is above pre-industrial levels and to study to limit the increase in temperatures to 1.5°C, to achieve this in less time there is process immediate reduction to net-zero emissions (MacMartin *et al.*, 2018). To this things are happening quite opposite that present commitments decreasing of CO₂ emissions are projected to result in warming closer to 3°C (Rogelj *et al.*, 2015). Approaches for ‘net-negative emissions’ carbon dioxide removal (CDR) is already impinged in future emission process, which is a strongly unrealistic scale. Nonetheless, over the period of overshoot, the technologies which are adopted now might bring the temperature to rise back below 1.5°C (Ricke *et al.*, 2017).

As per the figure, it is clear that solar geoengineering (or solar radiation management, SRM) could be considered as an alternative possibility to the other methods for maintaining long term climate damages. The purpose of solar geoengineering is to reduce climate changes by reflecting some sunlight back to space. The most frequently discussed approach is to inject aerosols or their precursors (e.g., SO₂) into the stratosphere the same mechanism by which large volcanic eruptions cool the planet. Another approach is marine cloud brightening (MCB), which aims to increase cloud albedo through injection of sea-salt aerosols the effectiveness of this is less certain (Latham *et al.*, 2012) (Table 1).

Other techniques have also been proposed, from space-based that are likely too expensive to land- or ocean-albedo modification that are either less scalable, have other environmental concerns (such as adding surfactants to the ocean), or are simply less well studied (MacMartin *et al.*, 2018).

Sulfate geoengineering is a proposed method to partially counteract the global radiative forcing from accumulated greenhouse gases, potentially mitigating some impacts of climate change. While likely to be effective in slowing increases in average temperatures and extreme precipitation, there are known side-effects and potential unintended consequences which have not been quantified. One such consequence is the direct human health impact (Pitari *et al.*, 2014; Effiong and Neitzel, 2016). Given the significant uncertainties, we take a sensitivity approach to explore the mechanisms and range of potential impacts. Using a chemistry-transport model, we quantify the steady-state response of three public health risks to 1°C global mean surface cooling (Eastham *et al.*, 2018).

The mechanisms by which an SRM proposal affects these outcomes can be separated into two categories: the “direct” impacts of the method, and the “RF (radiative-forcing)-driven” impacts. The figure below gives a conceptual overview of how these categories apply to the impact pathways between stratospheric injection of sulfate aerosol and human health impacts. “Direct impacts”, shown in black, include any effects of the technique which would occur even if there were no effect on the climate. For sulfate geoengineering, an example would be the descent of injected aerosol to the surface (Fig. 2).

SRM (solar radiation management) is not designed for reducing the concentration of GHGs (greenhouse gases) in the atmosphere; it only makes the warming effect. So, if SRM is used to make high-level warming and its distribution occur suddenly, temperatures would come towards the levels they would have reached without the geoengineering (McCusker *et al.*, 2012, 2014). This effect is known as “termination shock” or “termination effect”. This effect could be very damaging for nature and human

Table 1 Advantages and disadvantages of stratospheric geoengineering

Method	Confidence that substantial global ΔRF (e.g. $> 3 \text{ W m}^{-2}$) is achievable	Advantages	Disadvantages relative to stratospheric sulfate
Stratospheric sulfates	Very high: current technologies can likely be adapted to loft materials and disperse SO_2 at relevant scales	Similarly, volcanic sulfate gives an empirical basis for estimating efficacy and risks	
Other stratospheric aerosols	Moderate: depends on aerosol, lofting similar to sulfate but aerosol dispersal much more uncertain	Some solid aerosols have less start. heating and minimal ozone loss	Harder to bound uncertainty since not naturally occurring in the stratosphere
Marine cloud brightening	Uncertain: observations support wide range of CCN impact on albedo; substantial process uncertainty	Ability to make local alterations of albedo; and modulate on short timescales.	Only application on marine stratus covering approximately 10% of the Earth means RF inherently patchy
Cirrus thinning	Uncertain: deep uncertainty about a fraction of cirrus strongly dependent on homogeneous nucleation; no studies examining the diffusion of CCN	Works on longwave radiation so could provide better compensation	Maximum potential cooling limited; zonal distribution of RF constrained by the distribution of cirrus
Space-based	Low physical uncertainty, but deep technological uncertainties	The possibility of near 'perfect' alteration of the solar constant	Sustainably more expensive

Note: MacMartin, D.G., Ricke, K.L., Keith, D.W., 2018. Solar geoengineering as part of an overall strategy for meeting the 1.5°C Paris target. *Philosophical Transactions of the Royal Society A: Mathematical, Physical and Engineering Sciences* 376, 20160454.

Fig. 2 Impacts of sulfate geoengineering on humans. Reproduced from Eastham, S.D., Weisenstein, D.K., Keith, D.W., Barrett, S.R.H., 2018. Quantifying the impact of sulfate geoengineering on mortality from air quality and UV-B exposure. *Atmospheric Environment* 187, 424–434.

systems as the rate of warming is more than regularly expected climate under phylogeny climate change that means both human and ecosystems have less time to adopt that rapidly changing climatic conditions (McCormack *et al.*, 2016; Trisos *et al.*, 2018). Thermal shock can be defined as a rapid and strong rise in global temperatures that do the termination of SRM distribution (Parker and Irvine, 2018).

The United Nations Framework Convention on Climate Change has been working for reduction of greenhouse gas emissions to “avoid unsafe phylogeny interference with the climate system” (UNFCCC, 1992). Aerosol geoengineering links on offsetting the forces effects of greenhouse gas emissions with the forcing effects of aerosol emissions. The possibility of intermittent aerosol geoengineering forcing as well as negative impacts of the aerosol forcing itself may cause economic damages that far exceed the benefits (Goes *et al.*, 2011).

Models

In previous confer scientists gave their absolution on SG and to performed examinations using some models ensemble to know the agreement and disagreement of the models to following questions (Kravitz *et al.*, 2011).

- (1) Do CO₂ induced regional temperatures and precipitation values can be restored by global level geoengineering to diligence level?
- (2) Does the global scale geoengineering effectiveness depend on the amount of geoengineering?
- (3) Does an assessment of the effectiveness of global-scale solar geoengineering depend upon the relative weighting between temperature and precipitation?
- (4) Can we achieve the same effect as a transient one with continuous stratospheric aerosol and what extent precipitation would be compensated by a regional change in evapotranspiration?

To answer these questions some models are proposed which suites to standardized climate modeling experiment. For coordinating such experiments one framework is proposed that is known as Geoengineering Model Intercomparison Project (GeoMIP) (Kravitz *et al.*, 2011). The Program for Climate Model Diagnosis and Intercomparison (PCMDI) has consented to archive results from these experiments, so they can be openly studied. A number of simulations to be performed should be small because the Climate Model Intercomparison Project 5 (CMIP5; Taylor *et al.*, 2008) is already spreading the proficiencies of the modeling group.

Kravitz *et al.* (2011) used G1, G2, G3 and G4 codes to a suite of experiments. Simplest conceivable probes of balancing increased long-wave forcing with short-wave forcing are G1 and G2, i.e., by decreasing solar constant. From these experiments which are idealized to disclose the basic model retorts to the forcing balance without the added intricacies of conflicting treatments of stratospheric aerosol in various models. In this experiment, the author is trying to attain a perfect balance in radiative forcing but they are aiming to get the net balance as close to zero. From the results of this simulation validation of model has done as a part of GeoMIP runs. From a model control run, G1 experiment is introduced and will build on a CMIP5 simulation in which quadrupled CO₂ concentration can be observed promptly. Reduction in solar constant will balance global average radiative forcing from CO₂ this is done in G1. Radiative forcing of CO₂ is measured during CMIP5 quadrupled CO₂ run and the reduction in solar constant needed to compensate for force is done by a simple calculation using global average planetary albedo (Figs. 3 and 4).

After simulating a few years and monitoring radiative balance correction to this first estimation of the solar constant can be made. Both CO₂ radiative forcing and planetary albedo differ from one model to another so a different solar constant change may be needed. This change in solar constant is applied in G2 experiment (Figs. 5 and 6).

Experiment G3 is comparable with G1 and G2 but more realistic, that means it will give a scenario of execution of stratospheric geoengineering.

G3 assumes an RCP4.5 outline (representative concentration pathway, with a radiative forcing of 4.5 W m⁻² in the year 2100; Moss *et al.*, 2008) but with additional stratospheric aerosol added starting in the year 2020, which is a reasonable estimate of when the delivery systems needed to inject the aerosols, might be ready. To keep the planetary temperature about constant and balance phylogeny forcing stratospheric aerosol will be added progressively.

Experiment G4 similar to experiment G3 simulates a stratospheric sulfate aerosol layer. G4 involves the injection of stratospheric aerosols at a specific constant annual rate instead of attaining radiative balance, turned on precipitously in the year 2020. When uncertainties that can arise in evaluating the impact of geoengineering then results of G4 experiment will be helpful in assessing when the models are used to transmute emission ratio into concentrations. Authors base the proposed injection of aerosol rate is 5 Tg SO₂ per year on several considerations. Several estimates (Rasch *et al.*, 2008; Robock *et al.*, 2009) have implied that 3–5 Tg per year of SO₂ into lower stratosphere compensate a doubling of CO₂ concentration. 5 Tg SO₂ rate of injection per year interprets into 0.0137 Tg SO₂ per day as Crutzen (2006a,b), and Robock *et al.* (2009). Rasch *et al.* (2008) suggest 1.5 Tg of sulfur per year would be enough but Kravitz *et al.* (2011) proposed using 5 Tg SO₂ per year, to reduce the global average temperature to about 1980 values.

A group of simulations will be performed for each geoengineering experiment. The suggested method of generating each group and recommended size of groups will closely arrange with the protocol set by CMIP5 for simulations without geoengineering, additional group members will be developed if the results show in size of groups is insufficient to obtain statistically significant

Fig. 3 Schematic of experiment G1.

Fig. 4 Schematic of experiment G2.

Fig. 5 Schematic of experiment G3.

Fig. 6 Schematic of experiment G4.

results. In experiments G2, G3, and G4, the geoengineering will be applied for only the first 50 years, but with the courses extended an additional 20 years to examine the response to discontinuance of geoengineering.

Kravitz *et al.* (2011) used 12 models to obtain output for three simulations:

- (1) pi Control: a stable preindustrial control simulation.
- (2) Abrupt 4xCO₂: from the climate of pi Control, CO₂ concentrations are instantaneously quadrupled.
- (3) G1: the top-of-atmosphere net radiation changes in abrupt 4xCO₂ are offset by a uniform reduction in solar irradiance.

In each of these simulations, we carry out 12 models as well as we take the mean of 12 models to assemble. Temperature and perspiration average values over 11–50 are taken from the simulations. The climate in Abrupt 4xCO₂ continues to develop as well as in piControl and G1 has approximately reached steady state (Kravitz *et al.*, 2011; Tilmes *et al.*, 2013).

To calculate temperature and temperature and precipitation changes at the grid scale, both in absolute terms and normalized by the standard deviation of interannual natural variability in the piControl simulation $\sigma_{T, \text{piControl}}$, $\sigma_{P, \text{piControl}}$ (Kravitz *et al.*, 2011).

$$\Delta T_{\text{abrupt4} \times \text{CO}_2} = \frac{T_{\text{abrupt4} \times \text{CO}_2} - T_{\text{piControl}}}{\sigma_{T, \text{piControl}}} \quad (1)$$

$$\Delta P_{\text{abrupt4} \times \text{CO}_2} = \frac{P_{\text{abrupt4} \times \text{CO}_2} - P_{\text{piControl}}}{\sigma_{P, \text{piControl}}} \quad (2)$$

From Eqs. (1) and (2) where T (units of °C) and P (units of mm day⁻¹) are absolute values of temperature and precipitation, respectively, and ΔT and ΔP (unit less) are the absolute changes normalized by the standard deviation. To determine the temperature and precipitation partings from preindustrial levels for an arbitrary level of solar reduction g , denoted $\Delta T(g)$ and $\Delta P(g)$, we linearly interpolated between $\Delta T_{\text{abrupt4} \times \text{CO}_2}$ and ΔT_{G1} and between $\Delta P_{\text{abrupt4} \times \text{CO}_2}$ and ΔP_{G1} .

The response of temperature and perspiration to CO₂ and global – scale solar geoengineering had shown in this model closely linear in the range of forcing by doing the interpolation of the climate metric to different modes of solar reduction. The linear trend disdained levels of geoengineering that crossed the solar reduction in G1. Normalized level of solar reduction is defined as $g = \Delta S / \Delta S_{4 \times \text{CO}_2}$, where ΔS is a solar reduction, and the denominator denotes the reduction in solar irradiance that returns the globally averaged temperature to its preindustrial value ($g = 1$) (Kravitz *et al.*, 2011). 12-model ensemble average has been taken after calculating each model. In all calculations, g ranges between 0 (no geoengineering) and 2 (twice the required amount of geoengineering to return global mean temperature to its preindustrial value; also see Supplemental section 1).

The climate change metric D in a given Giorgi region I for a particular level of geoengineering g and weight w is defined by (Kravitz *et al.*, 2011):

$$D_i(w; g) = \sqrt{(1 - w)[\Delta T(g)]^2 + w[\Delta P(g)]^2} \quad (3)$$

w is a dimensionless weight parameter with values in $[0, 1]$. An equal weighting of ΔT and ΔP in calculating D corresponds to $w = 0.5$.

The dimensional quantities only make sense for the special cases of $w = 0$ and $w = 1$. In these cases, the equations for D degenerate into (Kravitz *et al.*, 2011):

$$D_i(g) = |g\Delta T_{G1} + (1 - g)\Delta T_{\text{abrupt} \times \text{CO}_2}| (w = 0) \quad (4)$$

$$D_i(g) = |g\Delta P_{G1} + (1 - g)\Delta P_{\text{abrupt} \times \text{CO}_2}| (w = 1) \quad (5)$$

For ease of assessing the results, one can also express D for precipitation changes in terms of percent change (Kravitz *et al.*, 2011):

$$D_i(g) = \left| g \left(\frac{P_{G1} - P_{\text{piControl}}}{P_{\text{piControl}}} \right) + (1 - g) \left(\frac{P_{\text{abrupt4} \times \text{CO}_2} - P_{\text{piControl}}}{P_{\text{piControl}}} \right) \right| \times 100 (w = 1) \quad (6)$$

Using the above model's calculations have done which were statistically not significant, i.e., a sign of change due to either CO₂ increases or solar reductions.

Effects of Solar Geoengineering

SRM (solar radiation management) can make a warming effect of GHGs (greenhouse gases) but not to reduce their concentration in the atmosphere. Therefore, if SRM deployment terminated suddenly while using to make high-level warming, the temperatures can be reduced by the levels that they would reach by the absence of geoengineering. This effect is known as “termination shock” or “termination effect” (Brovkin *et al.*, 2009). Natural and human systems will damage due to this termination shocks as the rate of increase in warming much higher than normal, as a result, both ecosystems and human systems have less time to adapt to the quick change in climatic conditions (McCormack *et al.*, 2016). By this, we can define a termination shock is a sudden and tolerable rise in global temperatures follows the termination of SRM deployment.

To occur termination shock there must be three criteria that need be satisfied: a large amount of SRM cooling, termination should be done suddenly, and SRM deployment should stay for a minimum period of time. To know better what would form a termination shock, we have to know answers to the following questions (Parker and Irvine, 2018):

- What is the time period for SRM cooling effect before possibility of termination shock?
- At what pace large scale SRM should be scheduled to avoid occurrence of rapid warming?
- For large scale SRM what should be the time length for causing substantial warming?

What is the Time Period for SRM Cooling Effect Before Possibility of Termination Shock?

Terminating SRM suddenly follows rapid warming. At the time of termination, the magnitude of warming will depend on the amount of cooling employed. Most of the modeling studies up to now have similar terminating scenarios, where SRM compensates the warming effect of GHG from decades, at the time of termination so that a sudden rise in global

temperature follows. At the same time, if the magnitude of deployment in SRM is very small, the risk will be a little and substantial rise in global temperature will not appear. The termination shock is defined with a threshold; it is possible to define a cooling threshold under which instantaneous termination of SRM will lead to less than the above threshold at the rate of warming addition. With evaluating the response of global temperature for an instantaneous change in forcing, leads to estimate threshold magnitude of cooling forcing. With simulations of Earth system model indicates that quadrupling of CO₂ concentration (an instant change in radiative forcing of about 7.4 W m^{-2}) instantaneously will respond around one half of equilibrium temperature response occurs within a decade, meanwhile three quarters within 100 years (Parker and Irvine, 2018).

At What Pace Large Scale SRM Should be Scheduled to Avoid Occurrence of Rapid Warming?

SRM deployment was stepped out adequately slow, then the warming rate could be limited, and we can avoid termination shock, even though it causes a very large cooling effect. By RCP 8.5 scenario limiting the rate of warming will imply stepping out SRM at a rate of 0.5°C per decade, but generally, it will be taken as dangerously rapid. With optimistic RCP 2.6 scenario limiting warming rate can expect minimum, 0.2°C per decade which shows stepping out of 50 years per degree Celsius cooling (Parker and Irvine, 2018).

For Large Scale SRM What Should be the Time Length for Causing Substantial Warming?

Rapid warming will follow; if something disturbs activities of large forming SRM deployment they were not stopped. Impact of disturbance would be much less for a full termination shock if SRM deployments were starts before a rapid increase in temperature. "Buffer period" length during the restoration of forcing would be determined by three factors:

- (1) Timescale of radiative forcing where decays of deployment activities starts.
- (2) Timescale for global temperature respond for radiative forcing changes.
- (3) Magnitude of forcing.

First, by sudden stoppage of deployment would not stop the aerosol to scatter the light which has been released in stratosphere, so radiative forcing on the climate is applied. For the observation of stratospheric aerosol the life time of aerosol is calculated which is approximately days, before they are washed out or fallen to the ground.

Second, for change in radiative forcing surface air temperature takes some time to adjust because earth's atmosphere and oceans will take time to warm. The whole process can't able to described by a simple e-folding time, but by observing we noted that for instantaneous change in forcing for one year the response of equilibrium warming is one quarter, for decade response is half and three quarters with in 100 years.

Third, if magnitude of forcing is smaller at the time of termination to cross the given threshold of warming it will take more time. For very large scale deployments which are leading to substantial rapid warming will take some time to cause some effect for the reasons mentioned above.

To classify physical dimensions that are responsible to lead termination shock to finalize that three conditions are followed to occurring of termination shocks

- (1) Deployment of SRM should cause a substantial cooling.
- (2) SRM deployment should be terminated suddenly.
- (3) Disturbance for deployment of SRM should continue for months or longer.

Considering physical characteristics of termination shock and analysis of schemes which are leading to termination statements below will describe them

- (1) To stop termination shock SRM should be maintained with a strong support.
- (2) Characteristics to make a robust and resilient SRM be relatively easy than most proposed elements of termination.

Global-scale solar geoengineering is the deliberate modification in climate system to balance some amount of manmade climate changes. By these changes differential effects in regional climate are resulting.

Conclusion

Partial restoration of global mean temperature to its preindustrial level could reduce the level of temperatures produced by mankind and also the perspiration changes by using a moderate amount of global scale solar geoengineering. Coming to Aerosol geoengineering it depends on counteracting the forcing effect by the emission of greenhouse gas with aerosol emission forcing effect. By the occasional aerosol geoengineering as well as the negative impacts causes economic damage which exceeds the benefits of aerosol forcing. More work in future to be needed to estimate the positives and negative consequences of solar geoengineering on biosphere and society, using more appropriate models and realistic problems.

Introduction

Mother earth is unique among planets since she has a suitable environment for the survival of living beings. The atmospheric conditions including temperature are maintained as such that life can exist comfortably here. But in the recent era several challenges have come upon humans to maintain these sustainable environmental conditions. One of the major challenges to mankind is to control climate change for which the responsible components are the greenhouse gases. The main contribution towards greenhouse effect comes from carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O) and chlorofluorocarbons (CFCs) (Mikkelsen *et al.*, 2010). All these gases are released in the environment due to human activities like burning of hydrocarbons in the engines of automobiles or production of electricity by combustion. CO_2 is one of the major greenhouse gas (GHG) in respect to its contribution to the global warming. Although Methane (CH_4) and Chlorofluorocarbons (CFCs) show much higher greenhouse effect as per unit mass basis, but CO_2 has about 60% contribution on the basis of its amount which is increasing continuously.

The main cause of CO_2 emissions is the increasing demand of energy requirement which is fulfilled by fossil fuel based electric power plants. Rapid industrialization includes enormous increase in the number of chemical plants which manufactures hydrogen, ammonia, cement, limestone and soda ash as well as implements fermentation processes and chemical oxidation processes. Urbanization, deforestation, over population, increasing automobile exhaust also contribute towards the increasing emissions of CO_2 .

One of the possible ways to control climate change is to minimize the amount of CO_2 present in the environment since CO_2 has a major contribution towards greenhouse effect. Though the capture of CO_2 has always been a challenging issue, it can be done by removal of carbon dioxide from the environment and its sequestration for purposes like several purposes. The probable methods of CO_2 capture includes three types of capture technologies namely pre-combustion capture, post-combustion capture and oxyfuel capture. One such process is the capture of CO_2 and its usage for generation of electricity by scrubbing with amines. Another method is by using molecular sieves or by membrane separation. These methods reduce the amount of CO_2 present but are either not cost effective or are not sustainable. Moreover, there are several barriers like energy requirements for chemical conversion of CO_2 , cost of co-reactants, limitations in market along with costs of capture, treatment, and transportation. As a solution, photosynthetic processes for sequestration of CO_2 have been considered in this study.

To reduce CO_2 emission three sustainable preventive measures can be opted. The first being reduction of energy intensity by its efficient use which is very difficult. The second requires use of non-fossil fuel such as hydrogen and renewable energy. The third one involves development of technologies to capture and sequester CO_2 . The technologies available for use of renewable energy sources are not mature enough, so still today fossil fuel dependency is unavoidable to meet the increasing demand of electricity. This makes the third option most viable to protect earth from the expected climatic changes.

Different Ways for Carbon-Di-Oxide Sequestration (CCS)

According to IPCC report 2005, Carbon Capture and Sequestration can be applied to large point sources. The captured CO_2 can be compressed and transported for storage in geological formations, in ocean, in mineral carbonates, or can be used as feedstock for industrial processes. Basically, there are three main routes of CO_2 capture systems: post-combustion, pre-combustion, and oxy-fuel combustion (Figueroa *et al.*, 2008). For post-combustion capture, CO_2 is sequestered from flue gas after the fuels being completely burned. Pre-combustion capture involves the so-called integrated gasification combined cycle (IGCC) system, i.e., the syngas generated from coal gasification consisting of CO and H_2 , is reformed by steam to produce a mixture of CO_2 and H_2 . The CO_2 is removed before H_2 is burnt in the combustion chamber of the gas turbine. In case of oxy-fuel combustion, coal is burned in nearly pure oxygen environment to produce flue gas having high concentration of CO_2 which can be stored or transported directly. Figueroa *et al.* (2008) summarized the advantages and disadvantages for all the three pathways. They believed that pre-combustion capture is applicable to gasification plants and oxy-fuel combustion can be applied to the newly built power plants. Presently all conventional coal-fired power plants combust fuels directly in a boiler to generate power (Merkel *et al.*, 2010). So post combustion capture as an "end-of-pipe" technology is more viable option for existing coal-fired power plants.

Many post-combustion capture technologies like chemical absorption (Rochelle, 2009), adsorption (Harlick and Tezel, 2003), membrane separation (Zhao *et al.*, 2008), Ca-Looping technology (Martínez *et al.*, 2016) and cryogenic fractionation (Hart and Gnanendran, 2009) etc., are proposed and being investigated these years.

Some of these are illustrated here.

Short Term Injection

Carbon-di-oxide can be relocated by direct injection into the sink capable of holding many mega-tones of gas over a period of time. Although this process helps to reduce global warming with immediate effect, most sinks will leak the sequestered CO₂ after a certain period of time.

Ocean injection

Ocean stores more CO₂ (estimated 38,000 Gt-carbon) than atmosphere (estimated 750 Gt-carbon) and terrestrial biosphere (estimated 2200 Gt-carbon). Annually ocean absorbs 1.7 ± 0.5 Gt from atmosphere. This natural process can be enhanced by direct injection. Depending on economic as well as technological grounds, "Droplet plume" and "Towed pipe" methods are suggested as most viable techniques for CO₂ injection in which liquid CO₂ is injected from a manifold below 1000 m, resulting in a rising plume or CO₂ is injected from a boat at a depth of 1000 m, resulting in a rising plume (Stewart and Hessami, 2005).

But this way of sequestration reduces the pH value of the deep ocean which affects the species like zooplankton, bacteria and benthos that are present in the non-swimming marine ecosystem at a depth of 1000 m or more (Stewart and Hessami, 2005). To resolve this problem and to utilize the delocalized CO₂ ocean fertilization can be opted. In this process the delocalized CO₂ is absorbed by the photosynthetic organisms. Their growth is stimulated by addition of nutrients. The dead organisms are decomposed by the microorganisms through the process of re-mineralization. But the resulting change in phytoplankton structure challenges the marine ecosystem. Additionally, the sinking organic matters decomposes anaerobic which may release other greenhouse gases like methane, nitrogen monoxide etc. which counteract the beneficial effects of carbon fixation (Yang *et al.*, 2008).

Geologic injection

Geologic injection refers to the process of fixation of CO₂ by converting the silicates to carbonates.

Mineral carbonation: This process involves chemical weathering that ensures the long term fixation rather than temporary storage and also reduces the risk of any accidental release of stored CO₂ from underground. In this process the CO₂ converts the silicates to carbonates by following reaction (Maroto-Valer *et al.*, 2005a,b).

The mineral carbonation happens naturally over geologic time scale. The process can also be accelerated by different artificial methods:

- (1) The reaction rate can be increased by enhancing the rate of dissolution of mineral ions by using strong acids. But the strong acids may cause damage to both the reaction facilities and environment (Yang *et al.*, 2008).
- (2) The reaction can also be operated under higher CO₂ pressure. But the higher CO₂ pressure will require intensive energy thereby increasing the cost of operation (Yang *et al.*, 2008).
- (3) The carbonation has also been studied by mechano-chemical process by University of Utah and University of Idaho (Nelson, 2004; Nelson and Prisbrey, 2004). In this process the natural silicates like forsterite, lizardite, wollastonite and synthetic materials like magnesium silicates were ground for a number of times in presence of gaseous CO₂. But the amount of carbon fixation was insignificant with respect to energy input for grinding activity (Nelson, 2004; Nelson and Prisbrey, 2004).
- (4) Mineral carbonation was also studied by surface activation to accelerate the reaction rate. Chemical activation was found to be more effective than physical activation in terms of increasing the surface area. The most effective chemical available for chemical carbonation was sulfuric acid and the process of steam activation was found to be the most effective one (Maroto-Valer *et al.*, 2005a,b).
- (5) Biomimetic process that involves biological catalyst was also studied for carbonation. The enzyme carbonic anhydrase increased the rate of precipitation of carbonate mineral significantly using industrial waste water as a source of calcium cation (Liu *et al.*, 2005).

Overall, mineral carbonation has limited scope as this technology requires a huge supply of metal oxides which will have a major impact on mineral industries (Yang *et al.*, 2008).

Enhanced oil recovery (EOR)

CO₂ can be injected in oil reservoirs to enforce the oil movement. The out-coming CO₂ can be recaptured and recycled for oil extraction. But the process of EOR is not feasible economically as it requires huge amount of energy for CO₂ removal. If the CO₂ recovery plant is combined with EOR, then the transportation cost can be reduced, still the process remains uneconomical (Stewart and Hessami, 2005).

Coal seams

Coal beds often contain methane gas. If CO₂ is adsorbed physically by porous structure of coal, then permanent retention of carbon is possible (Herzog, 2001). Reports has shown that using CO₂ instead water to flood the bed can recover methane more efficiently and sequester CO₂ as well (Beecy and Kuuskraa, 2001).

Technical Approach

The main problem for carbon capture and sequestration (CCS) is the increased cost of electricity that is required for the processes. In order to be accepted industrially, the cost of carbon capture should be minimum. Thus to obtain a cost effective process, different technologies like absorption, adsorption, membrane technology, hybrid treatment, biotechnology have been studied to compare the cost of chemical conversion and power generation.

Absorption process

Amine absorption process

- Absorption by amines is the most commercialized, mature and widely studied absorption technology. Different solvents like monoethanolamine (MEA), diethanolamine (DEA), methyldiethanolamine (MDEA), etc. are generally used in this process. Among these monoethanolamine (MEA) is mostly preferred because it reacts faster with CO₂ compared to other secondary or tertiary amines which allows absorption to take place in a smaller column. Reaction of mixed amines with CO₂ has also been studied and the cost of regeneration was found to be reduced. A comparison of performance between MEA with MEA/MDEA mixture (4:1 molar ratio) indicated that huge heat duty reduction can be achieved by using mixed solution instead of single MEA solution (Idem *et al.*, 2006).

Process description: During the chemical absorption process, flue gas enters a packed bed absorber from the bottom and counter-currently contacts with CO₂ lean solvent for absorption, then the CO₂ rich solvent flows into a stripper for thermal regeneration (Freguia and Rochelle, 2003).

After solvent regeneration, the produced CO₂ lean solvent is pumped back to the absorber to absorb CO₂ again. And the pure CO₂ is released from the top of the stripper which is then compressed to about 15 MPa for subsequent transportation and storage. The operational pressure for the whole system is approximately equal to the atmospheric pressure and the temperatures of the absorber and the stripper are generally in the range of 40–50°C and 100°–140° respectively (Metz *et al.*, 2005; Ciferno *et al.*, 2009). Theoretically, the minimum energy requirement for CO₂ recovery from power plants flue gas and for compression of CO₂ to 150 bar is 0.396 GJ/tonne CO₂. For operation in a power plant in real practice, 0.72 GJ/tonne CO₂ is to be achieved hopefully (Rochelle, 2009).

The proposed mechanism for CO₂ capture using amine is as follows:

Main problems and improving methods

Typical MEA process suffers the following disadvantages during separation of CO₂ from flue gas (Kittel *et al.*, 2009):

- (1) Low carbon dioxide capture capacity (g CO₂/g absorbent);
- (2) Amine degradation by SO₂, NO_x and oxygen in flue gas which induces a high absorbent makeup rate;
- (3) High equipment corrosion rate; and
- (4) High energy consumption for solvent regeneration.

To make the process more efficient, several promising investigations were done and improvements were considered:

- (i) Solvent utilization can be increased by increasing the gas-liquid contact area per unit volume with structured packing. The bed absorber was packed in a new structured way with different materials (like BX gauze, Flexipac, intalox saddle etc.) to improve the absorption efficiency and absorption rate compared to the traditional random packing. For structural packing 43.9% of solvent was utilized whereas in random packing it was only 28.6% (Yeh *et al.*, 2001).
 - (ii) Investigations were also done to develop promising solvents to enhance CO₂ absorption. Piperazine (PZ), a cyclic amine with two secondary amine nitrogen atoms is one of the promising solvents that have high absorption rate (Dugas and Rochelle, 2009), good capacity (Freeman *et al.*, 2010a,b) and good resistance towards thermal and oxidative degradation (Freeman *et al.*, 2010a,b). 2-amino-2-methyl-1-Propanol (AMP) and methyldiethanolamine (MDEA) were also considered because of relatively low energy consumption for solvent regeneration. But their reaction rate is low (Park *et al.*, 2006; Li and Lie, 1994). Blending of different alkanolamines was also done as it combined the advantages of different solvents and suppressed the disadvantages. Proper blending can result in high absorption rate for primary and secondary amines and lower solvent regeneration cost for tertiary and sterically hindered amines (Hagewiesche *et al.*, 1995).
 - (iii) Dilution of the aqueous fraction with organic solvents like methanol or ethylene glycol can also reduce the energy requirement for solvent regeneration as the organic solvents has lower heat capacity than water (Xiaomei *et al.*, 2014).
- Ammonium absorption process:

Aqua ammonium process can overcome the drawbacks of MEA process. In this process the flue gas is oxidized to convert SO₂ and NO into SO₃ and NO₂ respectively. After pre-treatment the flue gas is treated with aqueous ammonia in a wet scrubber. The byproducts of this reaction like ammonium sulfate and ammonium nitrate can be used as fertilizers but the use of ammonium

carbonate and ammonium bicarbonate is uncertain. So heat input is required to recycle ammonium from them. It was estimated that the process saves up to 60% energy compared to MEA process (Resnik *et al.*, 2004; Yeh *et al.*, 2005).

Adsorption process

The adsorption process is based on the same principle but uses porous adsorbents like zeolites, activated carbon, etc; chemical reaction between adsorbents and CO₂ may or may not occur.

- Molecular sieve adsorbent:

Molecular sieves are specially designed sieves used to separate molecules on the basis of their molecular weight or molecular size. Being mesoporous substrate the sieves have high surface area which incorporates organic adsorbent groups (generally amines). Then, the basic surface interacts with acidic CO₂ to form surface ammonium carbamate under anhydrous conditions and produces ammonium bicarbonate and ammonium carbonate in presence of water. Studies have been carried out with silica and MCM-48 as porous substrate and the CO₂ adsorption capacity was 0.5 mol CO₂/mol surface-bound amine group in absence of water (Yang *et al.*, 2008).

- Adsorption by activated carbon:

Anthracite, the best grade coal is capable of producing high surface area activated carbon. Studies have revealed that CO₂ capture does not show a linear relationship with increasing surface area. The highest CO₂ adsorption capacity was 65.7 mg CO₂/g adsorbent for the anthracite activated at 800°C for 2 h with a surface area of 540 m²/g. The anthracite with the highest surface area of 1071 m²/g only had a CO₂ adsorption capacity of 40 mg CO₂/g adsorbent. This could be explained by certain size pores being effective for CO₂ adsorption. Also the NH₃ treatment and PEI impregnation increased the CO₂ capture capacity of the activated anthracites at higher temperature due to the introduction of alkaline nitrogen groups on the surface (Maroto-Valer *et al.*, 2005a,b).

- Lithium compounds based adsorbents:

Lithium zirconate (Li₂ZrO₃) (Fauth *et al.*, 2005) and Lithium silicate (Li₄SiO₄) (Essaki *et al.*, 2004; Kato *et al.*, 2005) also exhibits CO₂ adsorption capability.

Among these lithium silicate is more desirable since it has larger capacity and rapid absorption. It also exhibits a wide range of temperature, concentration of CO₂ and stability (Essaki *et al.*, 2004; Kato *et al.*, 2005).

Membrane separation

Membrane separation depends on permeability and selectivity. Different membrane materials commonly uses ceramic (inorganic), polymeric (organic) and hybrid (mixed: organic and inorganic) membranes. Different modules also used spiral wound or hollow fibres. In this process, the flue gas is cooled by a wet scrubber before entering the membrane module. A portion of CO₂ permeates through the membrane and a stream (permeate gas) with higher concentration of CO₂ remains on the permeate side. The remaining part in the left side is called retentate gas. Compressor and vacuum pump are used to create pressure gradient between feed and permeate.

Although very few studies have been done on membrane separation compared to amine absorption, it has been concluded that the membrane-based separation process does not have apparent advantages over chemical absorption technology in terms of energy and cost at 90% separation degree (Wang *et al.*, 2017). Hybrid membrane-absorption capture system also has been studied. In the series arrangement, the flue gas is firstly treated in the chemical absorption unit and approximately 50% of the CO₂ can be removed. Exiting stream from the stripper with 10% CO₂ goes to the membrane unit. By this parallel set up 90% removal can be achieved and the volume of the flue gas decreases in the chemical absorption system due to which the absorber becomes half of the normal size. It is concluded that in this case the energy required for solvent regeneration is less and the capital cost is also less compared to conventional absorption process (Wang *et al.*, 2017).

Economic Concern and Environmental Issues

Most of the carbon capture and sequestration methods suffer from drawbacks. For example, oceanic and geologic injection can only delays the release of CO₂ in the atmosphere up to a certain time. Cost is also a major concern, as the carbon capture and sequestration increases the cost of electricity production. For example, MEA absorption leads to an increased cost of electricity by about 80% due to capture and storage of CO₂ (Mohamed *et al.*, 2017).

About the investment cost, for post-combustion it was estimated to be increased by 50% and for oxy-combustion by 65%, whereas for pre-combustion by 90% (Mohamed *et al.*, 2017). CO₂ capture process not only has to be economical but also environmentally and socially accepted.

In post combustion the ash particle emission gets decreased as the flue gas is washed by solvent and water. Still the process is not eco-friendly as amines can lead to gaseous, solid and liquid emissions which are potentially toxic for human beings and environment.

In amine absorption process there are three types of risks-

- (1) Solvent leakage and degradation of products;
- (2) Traces of emission of amine into the atmosphere;
- (3) Waste production in the solvent reclaimed.

Among these emission issue is most dangerous. Treated flue gas can contain traces of amine as a gas or aerosols which cannot be trapped by the flue gas water wash downstream in the absorption columns. The emitted amines and degraded amines may react in the atmosphere by complex mechanisms like photolysis, degradation and form more toxic elements like nitrosoamines (Shao *et al.*, 2009; Rohr and Show, 2012; Bratten *et al.*, 2009). Further, amines as a solvent not only reacts with CO₂, but also with NO_x and SO_x leading to form volatile compounds harmful to the environment.

Pre-combustion faces the same problems as post-combustion depending on the used solvent. However, unlike post-combustion, the treated syngas undergoes further combustion in the gas turbine. The issues of combustion of the pollutants that are generated by pre-combustion are not yet studied.

Considering all these facts, it is clear that the sustainable way of CCS is photosynthetic sequestration of CO₂.

Photosynthetic Sequestration

The most abundant and sustainable source of energy for Earth is the sun. More than 3800 zettajoules (1 zettajoule = 1×10^{21} joules) of solar energy are absorbed by Earth's atmosphere and surface annually. About 0.05% of this energy is captured in biomass each year through the process of photosynthesis (Hill *et al.*, 2006; Lewis and Nocera, 2006; Zhu *et al.*, 2008). The production, decomposition, and accumulation of biomass play a central role in the global carbon cycle. In a well-balanced ecosystem, carbon capture from photosynthesis, carbon deposition in the soil and oceans, and carbon release from biological and geological sources are in equilibrium. Since the beginning of the industrial age (in the 1850s), however, this equilibrium has been perturbed by increasing carbon emissions from the combustion of fossil fuel and biomass, and from reduced carbon uptake as a result of global deforestation and the loss of arable land.

Direct carbon combustion for energy production generates more than 24 gigatons of carbon dioxide (CO₂) annually (Lewis and Nocera, 2006) that causes rise in atmospheric CO₂ level leading to Global Warming. Hence it is very important to develop new method of CO₂ sequestration. It is also very important to develop a clean energy source which does not depend on fossil fuel and which have a tolerable environmental impact.

The first generation of biofuel production systems (starch- and sugar-based ethanol production) demonstrated the feasibility of generating liquid transportation fuels from renewable sources, but at initially low energy-conversion efficiencies and high cost. Fermentation of biomass to produce ethanol emits substantial carbon and yields a fuel that has only about half the energy density of oil-based fuels.

Hemicellulosic and cellulosic biofuel production systems enable the conversion of nearly all sugar-based plant polymers into fuels (ethanol, butanol, diesel). Plants that produce high levels of cellulosic biomass, such as *Miscanthus* and switchgrass, are being developed as second-generation biofuel crops. These biofuel crops do not compete directly with food production, require less agronomic (fertilizer, plowing, pesticide) inputs, and have lower environmental impacts than first-generation biofuels. However, some biofuel crops (*Miscanthus*) have the potential to be invasive species that may disrupt the biological integrity of local ecosystems (Raghu *et al.*, 2006). Overall, the energy efficiency, environmental sustainability, and economics of various renewable fuel production systems must be collectively evaluated to make informed decisions to identify the best energy production systems for each location and market. From the recent researches the scientists had come across the technique of carbon dioxide sequestration and biofuel production from micro and macro algae. This method becomes one of the alternatives to combat climate change as higher plants have various limitations to be used as a model system for carbon sequestration and biofuel production.

CO₂ Sequestration Using Algae

- What is algae:

Algae are eukaryotic organisms. Algae are recognized as one of the oldest life-forms. The true roots, stems or leaves are absent, they have no sterile covering of cells around the reproductive cells. Presence of chlorophyll and other pigments help in carrying out photosynthesis. Algae can be multicellular or unicellular. Depending on the species, algae can range from 1 micron (μm) to a few hundred microns in size. Microalgae are one of the most important groups of organisms on the planet. Mostly they are photoautotrophic and carry on photo-synthesis, some of these are chemo heterotrophic and obtain energy from chemical reactions as well as nutrients from pre-formed organic matter. Microalgae can fix CO₂ using solar energy with efficiency ten times greater than terrestrial plants (Wang *et al.*, 2011). Many species of algae are present such as; green, red and brown algae

which belong to the group of Chlorophyta, Rhodophyta and Phaeophyta, respectively. Algae belong to a wide range of habitat like freshwater, marine water, in deep oceans and in rocky shores. The Planktonic and benthic algae can become important constituents of soil flora and can exist even in such extreme conditions as in snow, sands/desert or in hot springs (temperatures above 80°C).

- Importance of algae:

It is estimated that microalgae produce approximately half of the atmospheric oxygen on earth, while consuming vast amounts of the greenhouse gas carbon dioxide. Microalgae have a rapid growth potential and many species have oil content in the range of 20%–50% dry weight of biomass (Falkowski *et al.*, 1996; Chisti, 2007; Metting, 1996). With respect to air quality maintenance and improvement, microalgae biomass production can effect bio fixation of waste CO₂ (1 kg of dry algal biomass utilize about 1.83 kg of CO₂) (Falkowski *et al.*, 1996). Nutrients for microalgae cultivation can be obtained from wastewater as a growth medium, thereby treating the organic effluent from the agro-food industry (Cantrell *et al.*, 2008). Algae can be grown under conditions which are unsuitable for conventional crop production like soybean and others. Algal cultivation does not require herbicides or pesticides application (Rodolfi *et al.*, 2008).

Algae is used as a source of food, fuel (oil, biodiesel, bioethanol, biohydrogen, and biogas), stabilizing agent (carrageen), fertilizer, chemical and in waste water treatment as well as in power plants to reduce CO₂ emissions and more. Algae provide much higher yields of biomass and fuels. Certain species of algae accumulated up to 60% intracellular lipid of their total biomass, it increases their heat of combustion and fuel value. Micro algae contain lipids and fatty acids are membrane components, storage products and as a sources of energy. More than 70,000 species of algae have been identified but all of them are not fit for human requirement. 50% of weight of algae is oil. The biofuel derived from Algae is non-toxic, contains no sulfur and is highly biodegradable (Singh and Singh, 2014). Fifty percent of the photosynthesis process takes place on Earth by algae (Goldman *et al.*, 1971). It removes inorganic carbon from the environment. Genetic engineering methods are improved micro algal photosynthetic rate to enhance CO₂ fixation and gain higher quantity of biomass to produce biodiesel and other important alternatives (Zeng *et al.*, 2011). They can also produce valuable co-products such as proteins and also biomass residue after oil extraction which may be used as fermented to produce ethanol or methane (Hirano *et al.*, 1997) or fertilizer (Cantrell *et al.*, 2008).

- Carbon capture by algae:

Cultivation of autotrophic microalgae on land in large ponds or in enclosed photo bioreactors using enriched carbon dioxide can help recycle this specific greenhouse gas. Algal growth is directly or indirectly gets affected various physical and chemical parameters such as light/irradiance/temperature/carbon-dioxide/pH/mixing; aeration, salinity etc. These autotrophic micro organisms are capable of converting CO₂ into carbohydrates and lipids in the presence of light by photosynthesis. Thus cultivation of microalgae can help to reduce the overall greenhouse gas emission when the algal biomass is converted into biofuel. Current research on oil extraction is focused on microalgae to produce biodiesel from algal oil.

Photosynthesis–fermentation model with double CO₂ fixation in both photosynthesis and fermentation stages has enhanced carbon conversion ratio of sugar to oil and thus provided an efficient approach for the production of algal lipid (Wei *et al.*, 2010).

The enriched carbon dioxide stream may come in the form of flue gases from power plant or may be obtained from other fossil fuel combustion and biological processes. Microalgae can be extensively used to capture CO₂ from power plants, steel, cement, oil, automobiles and many other industries and the resulting algal biomass can not only be used for biofuel production but also for various industrial products. Algae can reproduce very rapidly as compared to any other plants. With the cultivation of tens of thousands of algae, numerous CO₂ sinks can be developed which could be used to sequester CO₂ effectively through photosynthesis.

In general microalgae can be produced in open ponds or closed systems (such as photobioreactors) and the culturing methods used can be continuous, semi- continuous or batch (Jorquera *et al.*, 2010) (Table 1).

Direct utilization of power plant flue gas has been considered for CO₂ sequestration systems (Benemann, 1993). The

advantage of direct utilization of flue is the reduction of the cost of separating CO₂ gas. Since power plant flue gas contains higher concentration of CO₂, identifying high CO₂ tolerant species is important. Although CO₂ concentrations vary depending on the flue gas source, 15%–20% v/v is typically assumed. Several species have been tested under CO₂ concentrations of over 15% (Sharmila *et al.*, 2014). In Table 2, various algae are reported that easily grow at very high CO₂ concentration (Table 3).

- Photoautotrophic Production:

For large scale production of algae biomass for non-energy production, photoautotrophic production is the only technically and economically feasible method. Two systems based on open pond and closed photo-bioreactor are deployed for this purpose.

These systems make use of the natural process known as photosynthesis to convert light, heat and carbon dioxide to useful products, such as carbohydrates, hydrogen and oxygen.

The above equation illustrates a photosynthetic reaction. The type of product produced, in this case glucose, depends highly on the biological strain used in the photo-bioreactor (Figs. 1–2).

- Open pond system

Open ponds were extensively used in the past for the cultivation of algae (Fig. 3). Open ponds can be grouped into natural waters bodies such as lakes, lagoons, ponds and artificial ponds. Shallow Ponds are effective in algal growth as more sunlight penetrates into the shallow water. Shallow water also tends to be warmer, and this favors algae growth. In stagnant ponds, algae growth is favoured. The ponds in which the algae are cultivated are usually what are called the “raceway ponds”. In these ponds, the algae, water & nutrients circulate around a racetrack. With paddlewheels providing the flow, algae are kept suspended in the

water, and are circulated back to the surface on a regular frequency. Though open ponds are easier to construct, operate and easy to clean after cultivation, they have certain disadvantages. These disadvantages include poor light utilization by the cells, high evaporation rate, diffusion of carbon-dioxide into atmosphere resulting low biomass productivity (Fig. 4).

- Cultivation of Algae in Photobioreactor:

A photobioreactor (PBR) is closed equipment which provides a controlled environment and enables high productivity of algae. As it is a closed system, all growth requirements of algae are introduced into the system and controlled according to the requirements. PBRs facilitate better control of culture environment such as carbon dioxide supply, water supply, optimal temperature, efficient exposure to light, culture density, pH levels, gas supply rate, mixing regime, etc.

From the feeding vessel, the flow progresses to the diaphragm pump which moderates the flow of the algae into the actual tube.

The photobioreactor itself is used to promote biological growth by controlling environmental parameters including light. The tubes are made of acrylic and are designed to have light and dark intervals to enhance the growth rate. The photobioreactor has a built-in cleaning system that internally cleans the tubes without stopping the production. After the algae have completed the flow through the photobioreactor, it passes back to the feeding vessel. As it progresses through the hoses, the oxygen sensors determine how much oxygen has built up in the plant and this oxygen is released in the feeding vessel itself. It is also at this stage that the optical Cell Density sensor determines the harvesting rate. When the algae are ready for harvesting, they pass through the connected filtering system. This filter collects the algae that are ready for processing, while the remaining algae passes back to the feeding vessel.

Various researchers have investigated algal cultivation by changing various parameters.

Usui and Ikenouchi (1997) used a concave mirror to collect the light and passed the IR radiation to the bioreactor by fibre optics. The authors realized an improvement of 55% in overall efficiency by developing the light transmission system. These included developing a more sophisticated protective cover for the system, selecting an appropriate fibre optic diameter and optimising the ratio of fibre core area to bundle size. The light was distributed throughout the reactor by means of illumination plates consisting of a lattice of strips between two frosted acrylic plates. The experimental system experienced illumination of 10 h a day with 14 h darkness and achieved a CO₂ fixation rate almost 10 times that of a tree undergoing a natural photosynthetic process.

In designing a photo-bioreactor, Degen *et al.* (2001) made use of the “flashing light effect”. This is when the conversion of light to biomass can be enhanced by repeatedly cycling cells from the dimly lit interior of the reactor to the higher illumination of the exterior. Random cycling is not too effective. Degen *et al.* (2001) recommended a light-dark cycle of 1 Hz frequency with a light versus dark residence time of 1:10. In order to increase productivity, baffles were added.

Cultivation of algae in PBRs allows cultivation of algae in controlled environment, which leads to higher productivity. The other major advantages are – large surface to volume ratio, better control of gas transfer, reduction in evaporation of growth medium, attainment of more uniform temperature, much lesser probability of contamination, space savings.

The major drawbacks of using photobioreactor in algae cultivation are huge capital cost. Despite higher biomass concentration and better control of culture parameters, experimental data obtained in the last two decades have shown that the productivity in some enclosed photobioreactor systems are not very encouraging compared to those achievable in open-pond cultures. The technical difficulty in sterilizing these photobioreactors has hindered their application for algae culture for specific end-products such as high value pharmaceutical products.

- CO₂ fixation with wastewater treatment:

Microalgae feedstock production can be integrated with wastewater and industrial sources of carbon dioxide. CO₂ mitigation by microalgae production in wastewater is a beneficial technology to produce nutraceuticals, specifically beta- carotene, extracted from *Dunaliella* and *Spirulina* biomass (Benemann and Oswald, 1996). At the 272.40 mg/L/day CO₂ fixation rate, 70.42% biomass

was *Dunaliella Chlorella vulgaris* was cultivated in wastewater discharged from a steel-making plant with the aim of developing an economically feasible system to remove ammonia from wastewater and CO₂ from flue gas simultaneously. CO₂ fixation and ammonia removal rates were estimated as 26.0 g CO₂ m⁻³ h⁻¹ and 0.92 g NH₃ m⁻³ h⁻¹, respectively, when the alga was cultivated in wastewater supplemented with 46.0 g PO₄³⁻ m⁻³ without pH control at 15% (v/v) CO₂ (Sang Yun *et al.*, 1999). In another study, the feedstock potential of the Howard F. Curren Advanced Wastewater Treatment Plant (HFC AWTP) in Tampa, and the Wetland Treatment System of city of Lakeland, Florida have been estimated to be approximately 71 tons ha⁻¹ yr⁻¹ of algal biomass, 270,000 gal hr⁻¹ of liquid biofuel, and 415,000 kg yr⁻¹ of methane. Renewable energy derived from algae will play a significant role in providing energy security while important services such as water treatment can be synergistically achieved by these systems.

Conclusion

The world is faced with an intrinsic environmental responsibility, i.e., the minimization of greenhouse gas emission to acceptable levels. The mitigation of emissions of greenhouse gases, particularly CO₂, and their effective utilization present to the world both a difficult challenge and a major opportunity for sustainable development in energy and environment.

This study presented here attempted to explain the methods of carbon dioxide capture and sequestration and to discuss a line of research that may, in the future, help to reduce the greenhouse effect in a sustainable manner.

Different carbon dioxide capture techniques, such as amine scrubbing to treat flue gases, membrane separation methods, molecular sieve and desiccant adsorption technologies are proven technologies related to CO₂ sequestration but these capture and sequestration techniques would not have been economically feasible. Geologic and oceanic injection techniques also would not be sustainable. CO₂ conversion and utilization research is important and should be an integral part of research and development for carbon management and sustainable development.

Global strategy for control of CO₂ should begin with energy issues since the problem originates from the way the energy sources are selected and used. Among all processes of CO₂ sequestration, the natural process of photosynthesis, can be utilized to fix carbon dioxide and produce useful by-products in a sustainable fashion. The production of algae is identified as one of the solutions of carbon sequestration along with production of renewable fuel. It has been found that microalgae is capable to fix CO₂ from different sources such as from atmosphere, from flue gases discharged from industry as well as from soluble carbonates. The impact of various concentrations of CO₂ applied and its effect on algal lipid accumulation has been presented here which manifests a two-fold achievements namely reduction of an environmental problem by reducing one potential greenhouse emission as well as giving rise to a new form of renewable fuel, a valuable byproduct.

The Applicability of the Inflection Point in the Environmental Correction Process

Daniel Balsalobre-Lorente, University of Castilla La Mancha, Ciudad Real, Spain

Muhammad Shahbaz, Aviral K Tiwari, and Jose C Jabbour, Montpellier Business School, Montpellier, France

Introduction

It is not now that environmental problem has become relevant in economic growth theories (Since the Club of Rome was founded, a recurring economic problem has been the relationship between economic growth and public concern for environmental issues. The empirical EKC model is a popular means of analyzing the relationship between economic growth and environmental pollution. There is currently a large body of literature on EKC's ([Grossman and Krueger, 1991](#); [Selden and Song, 1994](#); [Hilton and Levinson, 1998](#))). Since the [Grossman and Krueger \(1991\)](#) established the existence of an inverted U-shaped relationship between environmental pollution and income, extensive research has been conducted in the field of Environmental Economics under the phenomenon of Environmental Kuznets Curve (EKC) ([Grossman and Krueger, 1991](#); [Stern et al., 1996](#); [Stern, 2004](#); [Dasgupta et al., 2002](#); [Dinda, 2004](#)). This has led to different theoretical argument on potential existence of a relationship between income and environmental pollution. The EKC model proposes a relationship between environmental quality and per capita income. This empirical hypothesis allows the incorporation of a set of additional variables that help to explain the EKC's behavior (e.g., how the potential impacts of public incentives on energy efficiency and energy innovation). In Addition, the EKC hypothesis shows that economic growth is friendly with environmental improvements. So, under the empirical evidence of a link between income and carbon pollution, we consider that analysis of inflection point provides an additional argument in order to accelerate the incorporation or regulatory measures, linked with energy efficiency and innovations, to control environmental degradation ([Balsalobre and Alvarez, 2016](#); [Álvarez et al., 2017](#); [Balsalobre et al., 2018](#)).

This approach seeks to incorporate a complementary exploration in the relationship between economic growth and environmental degradation, where regulatory policies that enhance energy innovations, many times requires public intervention aimed at improving economic growth and environment quality ([Iwata et al., 2010](#); [Turner and Hanley, 2011](#); [Balsalobre et al., 2015](#)). So, the implementation of innovation processes will contribute positively to environmental quality, placing countries on a path of sustainable economic growth ([Balsalobre et al., 2015](#)). To demonstrate this hypothesis, [Balsalobre et al. \(2015\)](#) employed the EKC model where they included additional explanatory variables linked with energy innovations.

Literature Review

While many studies have reported an inverted U-shaped relationship between economic growth and environmental degradation, there has been extensive research on the EKC hypothesis ([Shafik and Bandyopadhyay, 1992](#); [Ekins, 1997](#); [Grossman and Krueger, 1991](#); [Stern et al., 1996](#); [Stern, 2004](#); [Dinda, 2004](#); [Luzzati and Orsini, 2009](#); [Halicioglu, 2009](#); [Acaravci and Ozturk, 2010](#)). Since [Grossman and Krueger \(1991\)](#) reported inverted U-shaped between pollution and income relationship which is termed as EKC hypothesis. The empirical research on the EKC hypothesis has been extensively conducted and provided inconclusive empirical findings ([Shafik and Bandyopadhyay, 1992](#); [Stern et al., 1996](#); [Stern, 2004](#); [Dinda, 2004](#), among others). The EKC's analytic scheme, proposes a relationship between economic growth and environmental quality which implies that environmental degradation is an increasing function of economic activity, until it reaches a critical level, and then higher income levels lead to improve environmental quality, inverted-U shaped ([Selden and Song, 1994](#)). [Fig. 1](#), shows how environmental pollution increases till an economy reaches a certain income level (highest point) and thereafter economy experiences decreases in environmental pollution as the income level continues to grow.

[Fig. 2](#) represents a dynamic process where structural changes appears linked with economic growth ([Dinda, 2004](#)) which suggests that economic growth affects environmental quality via three channels such as scale effect, composition effect and technique effect ([Grossman and Krueger, 1991](#)). The *scale effect* asserts that, an increase in production will result in decreased environmental quality. This effect refers to the margin for new improvements to create increasing returns in terms of reducing contamination ([Torrás and Boyce, 1998](#)). The *composition effect* contains the impact on environment, since in the early stages of economic development, pollution increases as economic structure shifts from agriculture to more resource-intensive heavy manufacturing industries, whereas in later stages, pollution decreases as structure shifts toward services and light manufacturing industries. Otherwise, the *technical effect* refers to productivity gains and adoption of cleaner technologies, leading to increased environmental quality ([Andreoni and Levinson, 1998](#) argue that as economic activity increases, the level of environmental contamination is corrected, mainly through technological factors). This perspective links the EKC hypothesis with technological development, as the technical effect is stronger than the composition and scale effects. The technical effect refers to technological improvements that enable the use of less input per unit of output or the adoption of cleaner technologies to replace obsolete ones in the production of goods. Finally, [Andreoni and Levinson \(2001\)](#) argue that decontamination processes mainly depend on

Fig. 1 Inverted U-shaped EKC: Scale, Technical and Composition Effects.

Fig. 2 N-shaped EKC: Scale composition, technical and technical obsolescence effect. *Source:* Prepared by the authors based on Halkos, G.E., 2003. Environmental Kuznets Curve for Sulphur: Evidence Using GMM estimation, *Environment and Development Economics*. vol. 8, pp. 581–601. Cambridge University Press. Kaika, D., Zervas, E., 2013. The Environmental Kuznets Curve (EKC) theory- part A: Concepts, causes and the CO₂ emissions case. *Energy Policy* 62, 1392–1402. And Balsalobre, D., Alvarez, A., 2016. An approach to the effect of energy innovation on environmental Kuznets curve: An introduction to inflection point. *Bulletin of Energy Economics* 4, 224–233.

“technical effect”, as investment in innovation is going to contribute positively to reduce carbon emissions. Therefore, when the economies increase their income levels, it leads to higher energy consumption and lower rates of environmental pollution, due to a strategy of innovation with increasing returns to scale enable to improve energy efficiency. Recent studies reflect the existence of a technical obsolescence effect that appears when, in the long-run, the *scale effect* overcomes again the *technical* and *composition effects* (Balsalobre and Alvarez, 2016; Sinha *et al.*, 2017; Balsalobre *et al.*, 2018).

Among these different EKC shapes, our analysis focuses on the N-shaped pattern (Grossman and Krueger, 1995; Torras and Boyce, 1998; Shafik and Bandyopadhyay, 1992; List and Gallet, 1999; Álvarez *et al.*, 2017; Balsalobre *et al.*, 2018). In long-run, the N-shaped EKC hypothesis incorporates an extensive analysis, where technical obsolescence and inflection points can be explored (Balsalobre *et al.*, 2015; Álvarez *et al.*, 2017). This view was proposed by Opschoor and Vos (1989), who consider that, once the potential for technological improvement has been exhausted or becomes too expensive, increased income results in net environmental degradation. Otherwise, Torras and Boyce (1998) support the possibility of an N-shaped path of increasing contamination that could become manifest at reasonably high income levels. Economies might reach a path of increasing contamination if the scale effect overcomes the composition and technical effects when the margin for continuous improvement in distribution is exhausted or when the diminishing returns on technological changes to reduce contamination have been depleted.

The EKC also suggests the potential of public intervention in environmental affairs, and energy RD&D helps to understand this phenomenon. Thus, the regulatory processes involved in technological innovation offer an additional explanation, backed by the

endogenous theory: the income level/environment nexus is changed due to improvements in the production process as a result of technological change (Gradus and Smulders, 1993). Therefore, the technology used to reduce contamination also affects the EKC analysis, such that economic growth alone cannot solve contamination issues. When the effect of technological innovation is incorporated, thereby reinforcing the endogenous aspect of our hypothesis technological progress can be said to condition the income level-environmental contamination relationship, so that as energy technology improves, replacement with less contaminating energy sources and more efficient processes take place (Verdier, 1993).

In addition, the inflection point between first turning point X(1) and second turning point X(2) (Fig. 1) indicates that when the economy reaches a certain income level, society begins to pay less attention to environmental protection, and the scale effect can become dominant (Antweiler et al., 2001; Song et al., 2013; Balsalobre and Alvarez, 2016; Balsalobre et al., 2018). This pattern implies that economies are in a scenario where scale effects are stronger than composition and technical effects. Goklany (2012) argues that the inflection point indicates the peak corresponding to environmental transition is likely to move over time because of technical change and increased problems due to environmental degradation. In Fig. 3, the inflection point determines the income level at which scale effects start to overcome composition and technical effects, although these economies are decreasing carbon emissions (Balsalobre et al., 2018).

An Empirical Approach to Inflection Point in the EKC

The analysis presents the following reduced-form of the EKC model to test the presence of any potential relationship between income and environmental pollution:

$$ED_{it} = \alpha + \beta_1 GDP_{pc_{it}} + \beta_2 GDP_{pc_{it}}^2 + \beta_3 GDP_{pc_{it}}^3 + \beta_4 Z_{it} + \varepsilon_{it} \quad (1)$$

where ED refers to environmental degradation, GDP_{pc} is per capita income, and Z_{it} denotes a vector defining other factors that can potentially drive environmental degradation. The coefficient α shows the environmental degradation average when income has no special relevance for environmental degradation, while the coefficient β represents the relative importance of exogenous variables; ε_{it} is the error term, normally distributed with a zero mean and constant variance. A sub-index i indicates the country i , and t denotes the time dimension. The relationship between income and some measure of environmental quality is not monotonic and may present different shapes. Many studies that consider the link between economic growth and environmental degradation recommend an inverted U-shaped relationship (Fig. 1) (Grossman and Krueger, 1991; Selden and Song, 1994; Shafik, 1994, Panayotou, 1997). The EKC model can identify different relationship between environmental degradation and income, depending of β_1 , β_2 and β_3 coefficients ($\beta_1 = \beta_2 = \beta_3 = 0$ indicates a flat pattern or no relationship between x and y . $\beta_1 > 0$, $\beta_2 = \beta_3 = 0$ denotes a monotonic increasing relationship or a linear relationship between x and y . $\beta_1 < 0$, $\beta_2 = \beta_3 = 0$ indicates a monotonic decreasing relationship between x and y . $\beta_1 > 0$, $\beta_2 < 0$, $\beta_3 = 0$ denotes an inverted U-shaped relationship, i.e., EKC. $\beta_1 < 0$, $\beta_2 > 0$, $\beta_3 = 0$ supports a U-shaped relationship, while $\beta_1 > 0$, $\beta_2 < 0$, $\beta_3 > 0$ denotes an N-shaped curve. Finally, $\beta_1 < 0$, $\beta_2 > 0$, $\beta_3 < 0$ supports an inverted N-shaped curve). The EKC may not hold even in the long run (De Bruyn and Heintz, 1999). A so called N-shaped curve (Fig. 4) which exhibits the inverted-U shaped curve initially but beyond a certain income level the relationship between environmental pollution and income turns out to be positive, suggesting that the re-linking hypothesis may be plausible (Sengupta, 1996; De Bruyn and Opschoor, 1997).

The EKC's N-shaped behavior illustrates how an economy that reaches a certain income level (i.e., first turning point) also experiences decreases in its environmental pollution, with continued growth in income. Across the different shapes of the EKC,

Fig. 3 Inflection Point and Technical Obsolescence Effect.

Fig. 4 Turning points of the EKC model with regulatory variables and globalization. *Note:* The coefficients $\beta_1 > 0$, $\beta_2 < 0$, and $\beta_3 > 0$ indicate a cubic polynomial in an N-shaped EKC. The coefficients β_1 , β_2 , and β_3 also allow us to calculate the turning points in the cubic EKC model. (X_1) represents the first turning point and (X_2), the second.

this study focuses on N-shaped type of the curve (Grossman and Krueger, 1995; Torras and Boyce, 1998; List and Gallet, 1999). This N-shaped pattern is attuned with the consideration about the fact that technological improvements turn to be very expensive, with net environmental degradation resulting from increased income. An adequate environmental regulation policy could effectively accelerate technological changes, capable of decreasing contamination levels (Torras and Boyce, 1998).

Our study proposes an estimation of the relationship between income level and carbon emissions, including in the model a set of variables linked to energy regulation and environmental degradation. This model, which uses panel data for selected European countries (Denmark, Finland, France, Germany, Italy, Netherlands, Norway, Portugal, Spain, Sweden, United Kingdom) between 1990 and 2012, combines time-period and cross-sectional data. Using econometric techniques with panel data is adequate and extremely useful if there are non-observable heterogeneities in any specific country or during any time period. In our case, not every country makes decisions similarly, even if they share the same observable characteristics.

We therefore propose the following equation:

$$GHGpc_{it} = \alpha_i + \beta_1 GDPpc_{it} + \beta_2 GDPpc_{it}^2 + \beta_3 GDPpc_{it}^3 + \beta_4 RDD_{it} + \beta_5 RNW_{it} + \beta_6 GLOB_{it} + \varepsilon_{it} \quad (2a)$$

where: $GHGpc_{it}$ is CO₂ emissions, measured in metric tons (per capita) in country i and year t (WDI, 2017), $GDPpc_{it}$ is income per capita, measured in USD, at current prices and current PPPs, for country i and year t (WDI, 2017), RDD_{it} is public spending on energy RD&D, measured in USD, at current prices and current PPPs, for country i and year t (OECD, 2017) RNW_{it} is electric consumption (per capita) to each country's final, measured in ktop, for country i and year t (WDI, 2017). $GLOB_{it}$ is globalization. The descriptive statistics of the variables used are shown in Table 1.

It is necessary to pay attention to empirical results when the EKC N-shaped model is estimated for selected European countries between 1990 and 2012. The N-shaped behavior in the EKC means that when a cubic pattern equation is applied, a second turning point appears, where, beyond a given income level, carbon emissions once again begin to increase. This empirical approach shows how the income level ($GDPpc$) is needed to reduce carbon emissions ($GHGpc$) when a set of regulatory variables that help to

explain the evolution of carbon emissions is also included. These exogenous and complementary variables are the replacement of conventional energy sources with renewable ones (RNW) and public spending on energy innovation (RDDPC). For the result of the estimations, this study tries to verify the positive influence of energy innovation and electric use on carbon emissions. Otherwise, we hypothesizes that globalization entails a reduction in the CO₂ emissions.

The analysis of the income-pollution relationship poses certain potential problems. One such problem is the possible two-way causality between income and environmental degradation (Stern, 2004). Otherwise, it is known as an endogeneity problem, which means that some floating and explanatory variable correlates with the error term i.e. ε_{it} . We thus built a model, with instrumental variables for both regressions, without fixed effects in order to determine the correct coefficients of income (GDPpc_{it}, GDPpc_{it}², and GDPpc_{it}³). To capture the non-observables specific to each country that do not vary with time, the fifth regression is a fixed effects regression where GDPpc, GDPpc², and GDPpc³ are implemented with regard to age dependence and inflation, including both the square and cube of each instrument (Table 2).

In a first step, Model-1 is estimated, by *heteroskedasticity-corrected method*. The reduced form of the endogenous explanatory variable is obtained in function of the exogenous variables:

$$\text{GHGpc}_{it} = \alpha_i + \beta_1 \text{GDPpc}_{it} + \beta_2 \text{GDPpc}_{it}^2 + \beta_3 \text{GDPpc}_{it}^3 + \beta_4 \text{RDDPC}_{it} + \beta_5 \text{RNW}_{it} + \beta_6 \text{GLOB}_{it} + \varepsilon_{it} \quad (2b)$$

Discussion of the Results

This study examines the validity of the EKC hypothesis for selected European countries between 1990- and 2012 using heteroskedasticity-corrected method. We also check the relationship between energy innovations, renewable energy consumption, globalization and CO₂ emissions. The empirical results evidence that all variables are significant, confirming the robustness of the proposed model in Eqs. (2a,b).

The estimation of the coefficients (Eqs. (2a,b)) reveals that $\beta_1 > 0$, $\beta_2 < 0$, and $\beta_3 > 0$, confirming an N-shaped EKC pattern in Model-1 (Fig. 4). The first three coefficients β_i determine the cubic shaped of the EKC; the behavior of remaining coefficients also helps explain carbon emissions. This result indicates that initial stage of economic growth, GHGpc levels increase until GDPpc reaches a threshold point ($X_1 = \text{USD } 44,131.83$). Beyond that point, GHGpc levels start to decrease until GDPpc reaches a second turning point ($X_2 = \text{USD } 59,643.10$), (The estimation of the turning points for the cubic model used the following formulation (Diao *et al.*, 2009; Balsalobre and Alvarez, 2016)):

$$X_j = \frac{-\beta_2 \pm \sqrt{\beta_2^2 - 3\beta_1\beta_3}}{3\beta_3}, \forall j = 1, 2$$

To estimate the inflection point:

$$I_j = \frac{-\beta_2}{3\beta_3}, \forall j = 1$$

beyond which GHGpc levels start to rise again. Between first and second turning points appear Inflection $I(1) = \text{USD } 51,887.47$, which suggests that scale effect is able to overcome again composition and technical effects. This inflection point suggests that

economic systems need to accelerate innovation measures (technical effect) to delay scale effect, before these economies reach again a new stage of ascending emission levels (technical obsolescence).

To analyze this EKC's behavior and explain how energy regulations can help to delay the return to increasing GHGpc levels. The coefficient β_4 (Eqs. (2a,b)) represents energy innovations (RDD); the negative sign ($\beta_4 < 0$) suggests that innovation processes reduce GHGpc emissions. This result indicates that the implementation of regulatory policies in the field of energy innovations positively affects the correction of per capita GHG emissions (Balsalobre and Alvarez, 2016). In addition, the coefficient $\beta_5 < 0$ linked with renewable energy use (RNW) indicates that an increase in renewable electric consumption contributes positively to reduce GHGpc emissions. Therefore when economies stimulate innovation processes and renewable electricity use, by extension, the level of energy intensity decreases, helping to reduce GHG emissions (Lin and Polenske, 1995; Balsalobre and Alvarez, 2016; Álvarez et al., 2017).

An additional effect that has been explored in Eqs. (2a,b) is how globalization (GLOB) helps to control emissions. The coefficient $\beta_6 < 0$, which is negative and statistically significant, indicates that globalization process in selected European countries helps to reduce carbon emissions (Shahbaz et al., 2016a). We note that an increase in globalization leads to a decrease in CO₂ emissions. Cavlovic et al. (2000) establishes the existence of a direct relationship between low levels of globalization and high pollution intensity levels. Therefore our study suggest that both energy regulations and globalization help to control emission and delay technical obsolescence. This results also suggests that in the long-term, globalization might be expected to have a positive impact on economic efficiency (technique effect) and improve environment quality. Therefore, increased competition, which is shaped by globalization, will reduce technical inefficiency and pollution levels (Tisdell, 2001; Shahbaz et al., 2016b). This empirical evidence suggests that globalization process is environmentally friendly. This result is in line with previous empirical literature that considers the globalization process in terms of instruments of efficiency and technical progress.

The main objective of this study is to reflect the necessity of examine the inflection point, in order to improve the EKC analysis. According to the results obtained in this study, the scale effect in the EKC, specified by Torras and Boyce (1998), is justified. The way to solve the scale effect is by promoting energy innovation (RDD). When technical obsolescence appears, increasing income levels will lead to increasing environmental degradation (scale effect), which, in turn, will lead to the reemergence of an upward trend in carbon emissions per capita. The estimation of Model-1 incorporates public spending on energy RD&D, a variable that is compatible with our main hypothesis, which suggests that it is necessary to undertake measures to improve energy innovation, whether to correct or prevent environmental degradation. The N-shaped EKC relationship between income and environmental degradation suggests that, in the absence of measures to improve technical innovations, technological obsolescence leads to a return to a state of increasing environmental degradation. Andreoni and Levinson (1998, 2001) consider that the decontamination processes depend mainly on technical innovation. Therefore we suppose that technical effect dominance will depend on the incentives offered to policy makers and energy innovation measures (Heerink et al., 2001; Balsalobre and Alvarez, 2016).

Fig. 5 shows how the inflection point appears when, in long-term, scale effect overcomes composition and technical effect. This behavior is linked with technical obsolescence that implies that without the correct regulation process in the long term will be appear again an ascending stage of emissions (Balsalobre and Alvarez, 2016; Balsalobre et al., 2018). According with the results, $I(1) = \text{USD } 51,887.47$, when selected economies arise that inflection points starts there is a reduction in the positive effect of technical effect and composition effect on environmental quality. This point suggests that economies have to star to accelerate innovation processes before they reach that point. On the other hand, when scale effect overcomes composition and technical

effects, there is a deceleration of environmental correction process. In advanced economies, growth rates are generally low, such that technological change may overcome the scale effect implies that the quality of environment and technology are public goods, which makes government involvement necessary to keep a market economy on a socially optimal path.

Any strategy that seeks to reduce contamination levels must thus assume increasing returns to scale. In turn, we can infer that technical innovation is fundamental to control carbon emissions. When societies assume innovation processes it make environmental correction possible at lower incomes (Arrow *et al.*, 1995; Stigl, 1999; Unruh and Moomaw, 1998; Balsalobre *et al.*, 2015). Therefore, the implementation of measures related to energy innovation and the replacement of conventional sources with renewable ones results in a deviation from the diminishing technological returns, leading to a reversal in the upward trajectory of the EKC (Opschoor and Vos, 1989; Torras and Boyce, 1998; Balsalobre *et al.*, 2015).

To validate this hypothesis, we isolate the effect of energy regulation, omitting the variables RDD and RNW (Table 3) to demonstrate how the EKC performs (Model-2) and whether the turning points reflect the omission of the regulatory variable. This step is important in order to show how energy regulation and innovation policies are relevant to solve technical obsolescence.

$$\text{GHGpc}_{it} = \alpha_i + \beta_1 \text{GDPpc}_{it} + \beta_2 \text{GDPpc}_{it}^2 + \beta_3 \text{GDPpc}_{it}^3 + \beta_6 \text{GLOB}_{it} + \varepsilon_{it} \quad (3)$$

$$\text{GHGpc}_{it} = \alpha_i + \beta_1 \text{GDPpc}_{it} + \beta_2 \text{GDPpc}_{it}^2 + \beta_3 \text{GDPpc}_{it}^3 + \varepsilon_{it} \quad (4)$$

Model 2 (Eq. 3) omits the variables RDD_{it} and RNW_{it} is estimated, the turning points change, while model 3 (Eq. 4) just confirms the N-shaped model for selected countries between 1990 and 2012.

When we compare Model 1 (Eqs. (2a,b)) and Model 2 (Eq. 3), which omit the regulatory variables (RDD_{it} and RNW_{it}), in the main model (Model 1), the income requirements necessary to achieve reductions in carbon emissions per capita are lower ($X_1 = \text{USD } 44,131.83 < X_3 = \text{USD } 44,767.25$). Another consequence of the application of energy regulations is that income required to reach the second turning point, and, thus, to return to increasing pollution levels, is higher ($X_2 = \text{USD } 59,643.10 > X_4 = \text{USD } 57,259.79$). Another consequence of the estimation and comparison between Model 1 and Model 2 is that the former model can include a breakthrough in Fig. 1. Model 1 suggests the appearance of a new effect, which we define as the technical obsolescence effect (Balsalobre and Alvarez, 2016) that occurs as result of inadequate energy regulation strategy. When economies reach the state of technical obsolescence, it leads once again to an increase in environmental pollution levels. Otherwise, the inflection point of Model 2 (Eq. 3) reflects $I_2 = 51,013, 52 < I(1) = \text{USD } 51,887.47$, which implies that without regulatory measures scale effect appears sooner. So, the inflection point shows the income level necessary to take energy measures before economies reach the second turning point, and scale effect overcomes again composition and technical effect (technical obsolescence effect).

Conclusions and Policy Implications

Although the environmental Kuznets curve has been widely studied from both a theoretical and an empirical perspective, the various studies on EKC in the last decade have not been sufficient to provide a unanimous response in this field of study. This study constitutes an improvement in the analysis of the EKC pattern. The main objective of this paper is to analyze the inflection point between turning points and how it affects to carbon emissions. Our study including additional variables linked to energy

regulation, in order to validate that, in addition to economic growth, measures in the fields of energy innovations and the replacement of conventional energy sources with renewable ones are required to reduce carbon emissions. The results show an N-shaped relationship between income and environmental degradation.

This study demonstrates, through a heteroskedasticity-corrected econometric estimation for selected countries in the years 1990–2012 that regulatory measures and globalization help to reduce carbon emissions. The main model (Eqs. (2a,b)) proposed in this study demonstrates the relevance of environmental regulation measures to keeping countries on a path of decreasing carbon emissions per capita, even once they have attained high income levels. When economies' income levels increase, early on in the process of economic development, pollution levels rise. When income levels reach the first turning point, economies begin to experience corrections in their emissions. In a second stage, pollution levels begin to fall, in keeping with further increases in economies' income levels. This behavior is sustained until a second turning point is reached, after which economies once again begin to experience increases in pollution levels. Fig. 5 shows that without energy regulations (energy innovation and renewable energy promotion), economies may return to a pattern of increasing environmental degradation, a phenomenon that this study defines as the technological obsolescence effect, where inflection point has an essential role on this process. Consequently, to avoid this return to a path of increasing contamination, measures must be taken to encourage technological innovations and promotion of renewable sources, as not to fall into the trap of technical obsolescence.

This study tries to verify whether implementing environmental regulations has any effects beyond the EKC. In this regard, we have confirmed that, with the incorporation of energy regulations, second turning point, which is the consequence of technological obsolescence, can be pushed back. For this reason, regulations of energy innovation and renewable energy promotion help to delay the scale effect, according to which in the absence of regulatory measures, economies will once again see diminishing returns and increases in environmental pollution. The results also support the positive effect that globalization contributes positively to the reduction of carbon emissions.

Finally, the results obtained support the how the inflection point helps to advances in the analysis of the EKC. Finally, the results validate that environmental regulations should aim to provide incentives for innovation and the adoption of better abatement technologies. This study also points to the need for greater nuance in policy approaches aimed at energy innovation. Our results indicate that advances in energy processes are necessary to improve environmental quality. One of the most important conclusions that can be drawn from the EKC analysis is that environmental quality cannot wait until per capita income rises, as pollution will not automatically disappear with economic growth. This leads us to conclude that there is a strong need for European countries to develop specific policies in energy RD&D, energy replacement and globalization to reduce environmental pollution.

Introduction

From the year of 1760 onward Great Britain witnessed the industrial boom regarding the nature of machines where some particular works have been shifted to highly profiled special purpose machines from general purpose applications comprising of simple hand tools and basic home-made machines. Since then coal emerged to be the main source of energy in the entire world. It is an established fact that the energy sources may broadly be classified into conventional energy sources like coal, oil or natural gas, and renewable energy. The latter includes hydro power (water energy), wind energy, geothermal energy, solar power, and tidal energy, which are inexhaustible, clean, pollution free, and environmentally friendly. The source of electricity generation has been slowly shifting from conventional to renewable energy for the different advantages associated, with China, the United States, and the European Union as the frontline leaders in this respect.

The energy crisis that the earth is witnessing now is mainly related to limited use of the alternative energy sources and excessive dependence on the fossil fuel sources, which are supposed to be depleted within the next few decades. It is an alarming fact that despite several atmosphere threatening facts regarding the use of fossil fuel, 41% of the electricity generated worldwide uses coal as the source material causing emission of huge amounts of greenhouse gases. Also surprising is the fact that such unscientific use of fossil fuel is most acute in several developed countries like China, Australia, and other European states.

Now with the increasing environmental awareness, several countries having significant contribution towards greenhouse gases have stepped forward and discussed resolving the issues with severe climate change. In that list China is a mention-worthy country, which according to the United Nations Organization report is one of the main carbon dioxide contributors. Fig. 1 shows the current and projected energy consumption worldwide between 1990 and 2040 for both OECD and non OECD countries (see "Relevant Websites section").

The mechanical division extends to share the highest part of distributed power usage; global industries are expected to use more than 50% of energy in 2040. Though there are different international policies that impose critical limits on use of conventional energy, still it is predicted that there will be a 46% increase of CO ranging from 31 billion metric tons in 2010 to 36 billion metric

Fig. 1 World energy consumption, 1990–2040 (<https://www.linkedin.com/pulse/energy-crisis-causes-effects-remedies-naveed-ahmed-unar>).

Fig. 2 Growth in total electricity generation and total delivered energy consumption, 1990–2040 (<https://www.linkedin.com/pulse/energy-crisis-causes-effects-remedies-naveed-ahmed-unar>).

tons in 2020 and 45 billion metric tons in 2040. An aggregate of global power usage jumps from 524 quadrillion British Thermal Units (BTUs) in 2010 to 630 quadrillion BTUs in 2020 and 820 quadrillion BTUs in 2040.

It is no wonder that there is a tremendous effort worldwide to use renewable energy sources for the entire electricity needed, and in this aspect Denmark has achieved a commendable effort and produced 140% of their total electricity needed from wind power alone. Also the Scottish government has set an aim to generate 100% of the electrical energy needed with renewable sources by 2020.

In 2013, in a report entitled “International Energy Outlook 2013” the United States Energy Information Administration predicted that around 11% of the energy consumption is from renewable sources worldwide, which should be increased to 15% by the year 2040. On the other hand about 21% of the global power generation was from alternative sources like nuclear or other clean sources, which will be increased up to 25% by the same year. **Fig. 2** shows the corresponding statistics graphically (both existing and projected).

It is to be noted that there is always an imbalance between the energy consumed and energy generated associated with every country, which leads to the energy crisis. The situation can be understood if one analyzes the fact that the United States only has less than 3% of the global oil reserves and only 3.5% of gas reserves whereas Japan and China extract the major portion of their required energy from outside. On the other hand, the major raw energies are found in the vicinity of Gulf countries and Russia, which are however not big consumers of these. **Fig. 3** shows the existing and projected electricity generation from different sources up to 2040.

In another Asian country, like Pakistan, the distribution of energy is also mostly dependent upon the fossil fuel like gas (47.5%), oil (30.5%), coal (11.07%), and LPG (1.53%), which are of great concern. Presently the country is generating 35% of electrical power via hydel energy.

It would not be out of place to mention here that the alternative/renewable energies may be associated with greater installation cost and other installation hazards compared with the fossil fuels; however, they are associated with the pragmatic solution of the environmental issue as well as a gateway to balanced energy mix. It is to be noted that with the daily increasing demand of energy with limited supply of it this energy crisis brings economic demise enclosed with regional conflicts. Thus it is the perfect time to go for renewable energy to recuperate the global energy market.

Looking again back to the statistical analysis it can be seen that a country like China has done better than any other with investment of \$51 billion in alternative energy technologies and led the world in renewable power capacity with 70 total giga-Watts whereas in the same year that two figures for the United States are \$48 billion and 68 GW respectively. Germany took the third place in this aspect with \$31 billion investment with the total output capacity of 61 GW.

Germany's production of alternative energy, which provides nearly 11% of the country's energy needs, leads G-20 members (a group of finance ministers and central bank governors from 20 major economies), as stated by a 2012 report by the National Resources Defence Council. Indonesia follows, with roughly 6%, and next is the United Kingdom, at about 4%. The United States came in seventh, with only 3% of its electricity coming from renewable sources.

An extensive research led by Cutler Cleveland and team predicts that in the coming 50 years no country can produce renewable energy that alone can meet the entire energy requirement; however they also saw some commendable growth in some particular

Fig. 3 World net electricity generation by fuels (<https://www.linkedin.com/pulse/energy-crisis-causes-effects-remedies-naveed-ahmed-unar>).

Fig. 4 A look at the world renewable energy consumption in 2010. *Source:* Energy Transitions by Cutler Cleveland (https://file:///H:/Chapter%204/The%20Climate%20Crisis_%20Breaking%20the%20Fossil%20Fuel%20Habit%20_%20BU%20Today%20_%20Boston%20University.html).

sectors. For instance the cost of wind energy has decreased much due to the government subsidies and other improved technologies used. However another very promising energy sector, that is, solar energy needs to contribute substantially to the renewable energy sector.

Nuclear power, even though there are other low carbon energy sources, provides only 3% of the current world energy however it has an inherent drawback related to hazardous waste disposal and safety use making it less acceptable compared with wind or solar energy. In the developed countries like the United States, which has 65 operating nuclear power plants, people are not very keen on accepting it near their land because of the radioactive waste associated. Thus it may raise political issues if any government put extra effort in establishing new power plants.

Biomass such as switch grass, corn, or sugar cane converted to biofuel is another alternative source of energy, however, it associated with carbon exchange and thus again is not very environment friendly. **Fig. 4** shows the distribution in the use of renewable energy.

As per the extensive research work of Cleveland, it can be concluded that the best way to break the fossil fuel habit is developing a sustainable energy infrastructure using fossil fuel and with the help of these developed infrastructure one has to move slowly from coal and oil to renewable energy (see "Relevant Websites section"). Other associated policies taken by different governments like gas tax hikes, mandatory car-pooling to office/school/college, or mass awareness increase towards use of renewable energy can dramatically change the situation.

Fig. 5 Earth's surface, warmed by the sun, radiates heat into the atmosphere. Some heat is absorbed by greenhouse gases like carbon dioxide and then radiated to space (A). Some heat makes its way to space directly (B). Some heat is absorbed by greenhouse gases and then radiated back towards Earth's surface (C). With more carbon dioxide in the atmosphere later this century, more heat will be stopped by greenhouse gases, warming the planet (<https://scied.ucar.edu/longcontent/greenhouse-effect>).

Greenhouse Effect

The greenhouse effect is a phenomenon that causes the natural temperature of the planet to be above freezing. In principle the greenhouse effect is the net imbalance of the energy that comes from the sun into the planet and goes back into space. This effect results in imbalanced energy being absorbed and released by greenhouse gases. Though the effect is quite natural in our climate, the situation has grown alarming as due to basic human activity more and more greenhouse gases are generated and the atmosphere of the planet is getting warmer day by day (see "Relevant Websites section").

As mentioned before, Earth absorbs solar energy and reemits it into atmosphere in the form of heat. Due to the special molecular arrangement, a few gases called greenhouse gases can absorb much of it, which in turn they radiate back either to Earth's surface, to the atmosphere, or to another greenhouse gas molecule. Some typical examples of greenhouse gases are carbon dioxide, water vapor, methane, and nitrous oxide. The major constituent atmospheric gases nitrogen, oxygen, and argon, which are all diatomic and monoatomic, are not greenhouse gases. This is due to the fact that diatomic molecules like O₂ or N₂ have no net change in the distribution of their electrical charges or dipole moment when they vibrate. Also for monoatomic gas like argon there is no vibrational mode. Hence they are almost totally unaffected by infrared radiation. The heteroatomic molecules like carbon monoxide or hydrogen chloride absorb infrared radiation. However these molecules are short-lived in the atmosphere owing to their reactivity and solubility and this is the reason these gases do not significantly contribute to the greenhouse effect.

Fig. 5 shows the distribution of solar energy into Earth's surface.

It is to be noted that though the total amount of all the greenhouse gases is still very small as compared with the total atmospheric gases but they have tremendous effect on the climate of the planet. More alarmingly it can be predicted with perfection that due to excessive exhaustion of fossil fuel in the coming years the amount of carbon containing greenhouse gases will be doubled. Some farm animals release methane as they digest food, and during manufacturing of cement from limestone, carbon dioxide gases also gets released. The effect of presence of greenhouse gases is as follows. With more greenhouse gases in the air, heat passing through its way out of the atmosphere is more likely to be stopped. The added greenhouse gases absorb the heat. They then radiate this heat. Some of the heat will head away from the Earth, some of it will be absorbed by another greenhouse gas molecule, and some of it will wind up back at the planet's surface again. With more greenhouse gases, heat will stick around, warming the planet.

Energy Harvesting

What is Energy Harvesting

The process is alternatively known as energy scavenging or microenergy harvesting and is actually associated with capturing and reusing of readily available energy in the universe. The conversion is mainly into electrical energy, which can be of instantaneous use or can be stored for future applications. This process is useful mainly in places where it is difficult to install wind turbines or solar panels and power grids are not available. The captured energy can mainly be used for various applications like wireless applications, remote sensing, body implants, radio-frequency identification (RFID), and other applications at the lower segments of the power spectrum. When the energy harvested is not sufficient in making a small device run independently it can still make a battery run with longer lifetime (see "Relevant Websites section").

Why Harvest Energy

It is to be noted that the changing of batteries after a certain period is one of the major problems associated with low-power electronic devices. The problem mainly involves cost especially when there are hundreds of such devices like sensors involved, especially in remote locations. Energy harvesting technology on the other hand eliminates the need of replacing batteries regularly, providing almost infinite operating time to the battery. Thus the battery replacement becomes unnecessary where it is costly or not feasible or dangerous. Most energy harvesting systems are self-sustaining and practically require no servicing for many years. In addition, the power is used closest to the source, hence eliminating transmission losses and long cables. If the energy is enough to power the device directly, the application or device powered by the energy can operate batteryless.

Energy Harvesting Technologies

As mentioned before there are dedicated power conversion circuits that will be required for efficient collection, managing, and conversion of energy from different nontraditional power sources into usable electrical energy for different microelectronic devices like remote sensing, body implants, RFID, and others. The harvesting will be with the help of thermoelectric generators, piezoelectric transducers, and solar cells or others.

Harvesting kinetic energy

Kinetic energy originating from different vibrations, mechanical movement, etc. is collected and converted into electrical energy by a transducer, which is then rectified, regulated, and stored in certain thin film battery or supercapacitors. A few examples of proper harvesting and utilization of mechanical energy include a batteryless remote control unit where power is harvested from the force that one uses in pressing the button. The harvested energy is enough to power the low-power circuit and transmit the infrared or wireless radio signal. Another example is pressure sensors for car tires. In this application piezoelectric sensors are placed inside car tires from which they monitor the pressure and send information to the dashboard for the driver to see.

Harvesting RF energy

Here also the basic mechanism is the same. The antenna dedicated for receiving radio frequency signals pass the same to the associated transducer and thus the radio frequency gets converted to a DC voltage of 5.25 V capable of generating a current of 50 mA. In this way development of complete battery-free wireless sensor is possible, which finds applications in various fields like building automation, smart grid, defense, industrial monitoring, and more.

Harvesting solar energy

In this case light energy is converted to electrical energy with the help of photovoltaic cell. Here due to the intermittent nature of light the proper storage of energy is required. Thus the energy is used to charge a supercapacitor or battery to ensure a stable supply to the application.

The system found its applications in both industrial and domestic purposes, which include satellites, portable power supplies, streetlights, toys, calculators, and more. For indoor applications the typical intensity of the light used is not more than $10 \mu\text{W}/\text{cm}^2$. For indoor applications, light is usually not very strong and typical intensity is about $10 \mu\text{W}/\text{cm}^2$. It is to be noted that the power from an indoor energy harvesting system thus depends on the size of the solar module as well as the intensity or spectral composition of the light.

Harvesting thermal energy

Excess heat from industry is an abundant resource of unutilized energy that is primarily considered as a waste. The effective utilization of this heat energy, even up to a small percentage, may have significant effect on the energy efficiency of the fossil fuel utilization and also thereby mitigation of carbon dioxide, which would ultimately lead to a low carbon society. From the basic law of thermodynamics, whenever work is obtained from some resource such as fossil fuel, heat will be generated as a by-product. This heat energy remains untapped.

There are various innovative attempts to harness the waste heat to convert it into usable form of energy such as electricity. Various heat conversion technologies have already been developed with varying efficiencies. These include Rankine cycle, phase change material engine, thermophotovoltaics, and thermoelectricity.

Alternative Effective Fuel Generation

Even before 20th century, in 1896, Swedish researcher Svante Arrhenius was the first who predicted that constant use of fossil fuel can cause major problems like global warming. However nobody paid serious attention in this matter until the beginning of the 21st century.

When people realize that the use of fossil fuel should be decreased, the very obvious question that one has to face is what can be the possible replacement for conventional fossil fuel. All these alternative sources have their individual merits and demerits,

however, they all have substantial contribution towards the fields of alternative energy. These merits are related to the feasibility, efficiency, or cost (see “Relevant Websites section”). Considering all these, a few sources of alternative energy have been mentioned below.

Hydrogen Gas

Hydrogen gas is one of the most important alternative forms of energy, which is mainly associated with clean burning fuel producing only water vapor and warm air upon use, unlike other natural gases. It can either be extracted as the by-product of natural gases and fossil fuel emissions or can be generated by splitting of water through electrolysis. The first process denies its advantage due to the associated use of fossil fuel whereas the second one lacks the adequate generation of the product as per requirement. Present research has concentrated in generating hydrogen with much more efficiency to meet the supply/demand ratio properly.

Tidal Energy

Tidal energy has enormous potential to be one of the major contributors in the field of alternative energy. It can satisfy 20% of total electricity needed in UK. Mainly tidal stream generators are used to produce electricity from the kinetic energy of ocean without producing any waste. This is nothing but the production of electricity from tidal energy, resembling hydroelectricity generation.

Biomass Energy

Biomass energy is associated with the carbon emission; however, the rate of emission is lower than that from fossil fuel combustion. For domestic use, the maintenance cost is higher and one has to get permission from local government. This energy is not only associated with wood burning at low temperature but also associated with landfills and alcohol products.

Wind Energy

As the name suggests this energy is generated by using natural wind by means of wind turbine. This also produces no waste, keeping all other advantages regarding energy production the same. It is interesting to know that in the United States there are more than 20 million homes where only wind energy supplies all the required power and the number is increasing every day. Most of the nation here has some kind of wind energy set up and they have substantial investment regarding the growth of this particular technology.

Geothermal Power

Geothermal power has great potential to meet the energy requirements of around 40 countries and this particular energy sector has experienced a massive growth of 5% worldwide in the year 2015. This power is all about extracting energies from the ground around us without doing any acute harm to the land. However the sector has inherent drawbacks regarding the huge initial cost associated with the installation of power plants. This is the main reason that this form of energy with so much potential has not spread at the expected pace.

Natural Gas

Natural gas though has potential in different fields of applications like the vehicle industry for reduced rate of carbon emission; it also has the biggest negative issues compared with all other alternative energy sources associated with pollution. Further, natural gases emit greenhouse gases though the emission level is lower than that of fossil fuel. In last few years the demand for this form of energy has increased at a massive rate. In 2016, the lower 48 states of the United States reached record levels of demand and consumption.

Biofuels

This kind of alternative energy also has found its application mainly in the United States with around 7% of the transport fuel consumption supplied from this form of energy in the year 2012 and its use is increasing day by day. This energy, unlike biomass energy, uses animal and plant life to produce energy. The drawback is that the machinery needed for the proper extraction of the energy emits a considerable amount carbon.

Wave Energy

Wave energy also uses water energy like tidal energy, going further in that they can be placed in the ocean in various situations and locations. Like tidal energy its inherent advantage is the absence of any waste product associated with it. It is also more reliable than many other forms of alternative energy and has enormous potential when used properly. There are two major shortcomings regarding the extensive use of this form of energy: First is obviously the cost, and second is related to less knowledge regarding its effects on natural ecosystems.

Hydroelectric Energy

Hydroelectric energy is one of the oldest forms of energy where the electricity is generated by means of water turbine. However due to the rise of fossil fuel the use of this form of energy has been decreased rapidly still they supply the 7% of total energy produced in the United States. It has advantages of being renewable as well as a clean source of energy. Also it has some associated advantages like flood control by the dams raised for generating electricity.

Nuclear Power

Nuclear power plants generate a quarter of the electricity in 12 countries around the world with more than 450 plants working worldwide. It is mention-worthy that this power is amongst the most abundant forms of alternative energy. This has advantages regarding emission, efficiency, and moreover regarding the creation of jobs in the field of power plant development and maintenance. However, it has drawbacks regarding the definite catastrophe associated with sudden breakdown of the plant.

Solar Energy

Solar energy is the most popular form of alternative energy and has shown tremendous potential in solving the energy issue. In the last couple of decades much of the alternative energy related research has been focused on this form of such energy. A number of countries have introduced initiatives to promote the growth of solar power. The United Kingdom's Feed-in Tariff is one example, as is the United State's Solar Investment Tax Credit.

This energy source is renewable in all senses and though it seems costly at the time of installation, this cost can be counter-balanced by the money saved in energy bills compared with the traditional energy sources. Nevertheless, solar cells are prone to deterioration over large periods of time and are not as effective in unideal weather conditions.

An Introduction to Thermoelectric Phenomena

Thermoelectric effect involves generation of electricity due to temperature gradient existing over a thermocouple. The effect can be classified into three categories: Seebeck effect, Peltier effect, and Thomson effect.

Seebeck effect is associated with the generation of electricity in a thermocouple when one junction is kept at lower temperature while the temperature of the other junction is raised.

Peltier effect is completely different from Joule heating, and involves generation of temperature gradient when current is applied.

In contrast with the previous two effects the *Thomson effect* involves single conductor instead of thermocouple. Here, if two points of a conductor of the same material are maintained at different temperatures then there exists an e.m.f between these points. So there will be evolution or absorption of heat in excess of Joule heat when a direct current passes through a non-uniformly heated conductor. It is also a reversible phenomenon.

The efficiency of a thermoelectric material is determined by the dimensionless figure of merit, where S is the thermoelectric power, defined as the

$$ZT = \frac{S^2 \sigma}{\kappa} T \quad (1)$$

Here, σ is the Seebeck coefficient, κ is the total thermal conductivity consisting of both phonon and electronic contributions, and T is the temperature. The efficiency is related to ZT by the following equation:

$$\eta = \frac{\Delta T}{T_{Hot}} \frac{\sqrt{1 + ZT} - 1}{\sqrt{1 + ZT} + \frac{T_{Cold}}{T_{Hot}}} \quad (2)$$

where T_{Hot} is the temperature of the hot junction and T_{Cold} is the temperature of the cold junction. One immediately sees that the efficiency tends towards the Carnot limit when ZT approaches infinity. To compete with modern-day compressor based refrigerators, a thermoelectric device must have a $ZT > 3$.

There is no theoretical limit to ZT . To maximize ZT , P must be large so that a small temperature difference can create a large voltage, σ must be large to minimize joule heating losses, and κ must be small to reduce heat leakage and maintain a temperature

difference. P , S , and κ are not, however, mutually exclusive. For instance in a bulk material, the Weidmann–Franz law limits the ratio σ/κ_e , where κ_e is the electronic contribution to the total thermal conductivity. Also, a sharply peaked density of states favors large S , but the density of states is a smoothly varying function for bulk materials. Nanowires may offer the possibility to circumvent some of the materials limitations found in bulk. First, the thermal conductivity has been shown to decrease when the size of a material is reduced to the nanoscale. Second, the thermopower is sensitive to the density of states and phonon–electron scattering, which may be very different in certain materials at the nanoscale. To increase ZT , a better understanding of the interplay between the three materials parameters, P , S , and κ , must be developed.

Electronic Theory for the Generation of Thermoelectricity

The reason behind thermoelectricity is mainly dependent upon the transport phenomena of the charge carrier, that is, electron. When two metals are brought into contact with one another the electrons from one metal start to flow into the other one, making first one positive and the second metal negative. Thus an e.m.f. gets developed across the junction trying to prevent the further electron diffusion. This e.m.f., also known as contact e.m.f., is equal to the difference between the work function of the two metals. Now, if both the junctions of the thermocouple are kept at the same temperature the as-grown contact e.m.f. nullifies each other and no net electron flow occurs.

However the contact e.m.f. depends slightly on temperature and thus a net e.m.f. gets developed when two junctions of the system are kept at different temperature. Also due to the higher thermal energy the electrons diffuse more rapidly from the hot end to cold end than from the cold to hot end, and give rise to the volume component of the thermo e.m.f. Also at low temperature another component of thermo e.m.f. may contribute, which comes from the phonon assisted drag of electron from hot to cold end.

The Peltier effect can be explained with the assumption of using an external battery to send current through the junctions maintained at same temperature. In one junction the current is flown against the contact e.m.f. and thus the work has to be done against it and heat gets generated. Similarly in the other junction the current flows down along the direction of the contact potential, hence the work is done by it and as consequence the junction gets cooled.

The effect can alternately be explained in other ways. Let the average carrier energy of metal I and metal II be w_1 and w_2 ($w_1 > w_2$) and let the direction of current be such that carrier passes from metal I to II at one junction. Then the carriers of metal I give up excess energy at a region very near to the junction and thus the junction gets hot. Similarly in the other junction carrier moves from II to I and the less energized carriers absorb energy and consequently the junction gets cold. This accounts for the observed Peltier effect.

Thomson effect can also be explained from the same point of view. It should be noted that the electrons from the hot end thus would diffuse into the metal faster than those from the cold side. Thus during the passage of electrons from the hot side it loses energy due to collision with the lattice in the colder side and causes evolution of Thomson effect. However this theory is too simple and cannot account for the fact that for some metals, the effect is positive, whereas for others it is negative.

Band theory of solids can explain the work more vividly. Electrons from the hot end have more energy and higher wave number value. Their velocity depends on the shape of E – k curve near the top of a band. If $\frac{d^2E}{dk^2}$ is negative then the velocity $v = \frac{2\pi}{h} \frac{dE}{dk}$ of the electrons from the hot end would be lower compared with that from the cold end and as a consequence the electron would diffuse more rapidly from the cold end contrary to the previous expression. This would give rise to an e.m.f. of opposite sign to that we should expect from free electrons.

Some Efficient Thermoelectric Materials

So far a number of potentially important thermoelectric materials have been discovered and studied widely. From the long list only some important materials are mentioned below. In this context, the material Bi_2Te_3 is mention-worthy at the beginning.

The material has strong anisotropy associated with its properties and a strong correlation between electrical conductivity and the stoichiometric composition of the material can be observed. It has very high vacancy induced defect density, as high as 10^{21} cm^{-3} . This has direct consequences with strong scattering of carriers causing substantial decrease of the mobility. The inherent low melting point (585°C) and small bandgap (0.16 eV at 300K) makes it suitable for using it in low temperature region ($\leq 150^\circ\text{C}$). A suitable substitution can make the material p-type (As, Sb, Pb) or n type (I and Cu). Bi_2Te_3 based materials have low band gap (0.16 eV at 300K) and thus are used at low temperature in thermoelectric cooling devices. The band gap and hence the operating temperature of the material can be increased up to 950K with suitable replacement of Te by Se ($\text{Bi}_2\text{Te}_{3-x}\text{Se}_x$), which may double the band gap of the material for optimum value of x .

The materials operated between temperature ranges 450–950K are medium-temperature thermoelectric materials for which an optimum band gap of ≈ 0.6 eV is needed; however some exceptions of lower band gap materials can also be seen. Chalcogenide materials like PbTe, PbSe, and GeTe are good examples of medium-temperature thermoelectric materials having operating temperature between ambient and 625°C . Fig. 6 shows the temperature variation of ZT values for medium-temperature thermoelectric materials.

Semiconductors like silicon or germanium in their elementary forms have high thermal conductivity and low figure of merit values and thus are not much suitable for thermoelectric applications. However a Si–Ge solid solution thermal conductivity decreases substantially and thus they can be used as high temperature thermoelectric material with operating temperature $\sim 1000\text{K}$.

Fig. 6 Temperature variation of ZT values for medium-temperature thermoelectric materials. Reproduced from Sherchenkov, A.A., Shtern, Y.I., Mironov, R.E., Shtern, M.Y., Rogachev, M.S., 2015. Current state of thermoelectric material science and the search for new effective materials. *Nanotechnologies in Russia* 10 (11–12), 827–840.

Also there is search for a new material that has strong scattering of phonons with low thermal conductivity and high transport properties (Slack, 1995). This kind of material is called phonon glass–electronic crystal (PGEC), having less thermal conductivity high transport properties of charge carrier. The concept was proposed by J.A. Slack in 1995.

As per Slack's idea, in PGEC one atom is weakly attached to the other atoms of the unit cell experiencing nonharmonic oscillation, which is independent of the fluctuation of the other atoms in the unit cell. This oscillation reduces the phonon components of the thermal conductivity and thus the value of the latter reduces significantly while keeping the electrical property of the material almost unchanged significantly enhancing the figure of merit value.

A set of materials that belongs to PGEC category are called skutterudites, which came from the mineral based on CoAs_3 . Other skutterudites include the materials with similar structures like CoP_3 , CoAs_3 , CoSb_3 , RhP_3 , RhAs_3 , RhSb_3 , IrP_3 , IrAs_3 , and IrSb_3 , having the general formula of MX_3 . Fig. 7 shows that at room temperature these kinds of materials have small ZT value ~ 0.2 , however, at 1000K ZT has a value ~ 1.4 exceeding that of SiGe solid solution.

Another set of materials analogous to PGEC are called clathrates, which are in principle composed of ten to hundred atoms of crystalline materials. Here the structure is formed by the formation of covalently bound frame of atoms and loosely connected with the frame of atoms or molecules located in the cavities. In case of semiconductor clathrates the framework is formed with different group IV elements like Si, Ge, and Sn, which can be substituted by nontransition elements like P, As, Sb, Bi, Al, Ga, In, and Te or transition metals like Ni, Pd, Pt, Cu, Ag, or Au. However substitution should be in small amounts in the case of transition elements.

So far clathrate $\text{Sr}_8\text{Ga}_{16}\text{Ge}_{30}$ is reported to have the highest ZT values at 0.35, which is however much less compared with the values of established thermoelectric materials.

An abnormally high ZT value of ~ 2.3 along the c -axis and ~ 0.8 along the a -axis has been reported for the material SnSe at 923K (Zhao *et al.*, 2014). Also high value of ZT can be found for the material Zn_4Sb_3 . A set of materials with modified Bi_2Te_3 structures with the structure of tetradymite and blocks of tellurides of arsenic, lead, or germanium with the adjusting structure attracted the current researchers as efficient thermoelectric material. $\text{Ge}_2\text{Bi}_3\text{Te}_5$, GeBi_2Te_4 , GeBi_4Te_7 , and $\text{GeBi}_5\text{Te}_{10}$ are few examples of such materials.

Some other promising thermoelectric materials are Na_2CoO_4 , CaMnO_3 , $(\text{ZnO})(\text{In}_2\text{O}_3)$, ZnO , and CuAlO_2 (Sugihara, 2005). Among these, CuAlO_2 has been discussed in detail in the next section. All of them are stable at high temperature, but the problem in dealing with them as thermoelectric materials lies in the fact that it is not easy to ensure low contact resistance and there may be cracking due to large mismatching of coefficient of thermal linear expansion between working material and that of the electrode.

CuAlO₂: An Efficient Thermoelectric Material

As mentioned before, the conventional thermoelectric materials like Bi_2Te_3 , PbTe , and SiGe alloys have limitations with use over 1000K. At the same time, materials like doped FeSi_2 remain active over 1000K, but their performance is not satisfactory. Thus to

Fig. 7 Temperature dependence of ZT for some thermoelectric materials. Reproduced from Sherchenkov, A.A., Shtern, Y.I., Mironov, R.E., Shtern, M.Y., Rogachev, M.S., 2015. Current state of thermoelectric material science and the search for new effective materials. *Nanotechnologies in Russia* 10 (11–12), 827–840.

make a balance, other conducting oxide materials like $(\text{Zn}_{1-x}\text{Al}_x)\text{O}$, $(\text{Zn}_{1-y}\text{Mg}_y)_{1-x}\text{Al}_x\text{O}$, $(\text{Ca}_{1-x}\text{Bi}_x)\text{MnO}_3$, $\text{CdIn}_{2-x}\text{Sn}_x\text{O}_4$, Cd_2SnO_3 , $\text{Cd}_2\text{Sn}_{1-x}\text{Sb}_x\text{O}_4$, $\text{In}_2\text{Te}_{1-x}\text{Re}_x\text{O}_6$, etc. have received much attention for possible applications over a wide temperature range.

Also we have seen the dimensionless figure of merit, which is the measure of the performance of the material as thermoelectric material increases with higher values of σ and λ . However when σ and λ increase the thermal conductivity also changes as per Wiedemann–Franz law and thus figure of merit remains almost constant.

Materials with delafossite structure MIMIIIO_2 (where $\text{MI}=\text{Cu, Ag, Pt, Pd}$; $\text{MIII}=\text{Al, Ga, In, Cr, Fe, Co, etc.}$) possess natural layered structure. Thus it can be used as promising thermoelectric material as per Hicks' model. Like the materials mentioned above, polycrystalline CuAlO_2 thin film is a p-type transparent conducting oxide, which has tremendous potential to be used in optoelectronic device technology. A few years back Koumoto *et al.* (2001) reported the efficient thermoelectric properties of CuAlO_2 single crystal.

Also there are reports regarding the same from different researchers worldwide. For instance, Ruttanapun *et al.* (2014) found ZT of solid state synthesized bulk CuAlO_2 powder to be 0.017 at a 960K. In the same year Suriwong *et al.* (2014) synthesized the same material by direct microwave heating and found the value of ZT to be 0.009 at 1073K. Akyildiz (2015) reported the synthesis of the material by coprecipitation method and studied its electrical property. In 2015, Lu *et al.* reported the fabrication of thermoelectric CuAlO_2 and performance enhancement by high density and found the highest value of ZT to be $5 \times 10^{-3} \text{ K}^{-1}$ at optimum density value.

Electronic structures and thermoelectric properties of delafossite 2H-CuAlO_2 have been theoretically investigated by Poopanya (2015) using first principles calculations and Boltzmann transport equation. Sakulkalavek and Sakdanuphab (2016) reported doped p-type oxide with Ag_2O to enhance the thermoelectric properties of CuAlO_2 and got the highest value of ZT as 5×10^{-3} at 873K. The same substitution into the same material gives the value of ZT as 0.0044 at 573K, from a sample containing 0.2 at% Ag_2O as reported by Pantian *et al.* (2017). CuAlO_2 thermoelectric compacts by spark plasma sintering and thermoelectric performance improvement by orientation control has been reported by Hao *et al.* (2017). Temperature dependency of thermoelectric properties of CuAlO_2 has been studied by Feng *et al.* (2019) who found the highest values of ZT to be 0.27×10^{-2} at 780K.

Synthesis of CuAlO_2

There are numbers of ways for the synthesis of the material, a few of which has been invented and reported in the author's previous work. The experimental includes simple solid-state reaction (Banerjee *et al.*, 2005a), sol-gel synthesis (Ding *et al.*, 2010), or dc-sputtering (Banerjee *et al.*, 2005b). Apart from that, there are others methods like pulsed laser deposition (Yousheng *et al.*, 2014), chemical vapor deposition (Cai and Gong, 2005), reactive solid-phase epitaxy (Ohta *et al.*, 2003), thermal coevaporation (Jayaraj *et al.*, 2001), electron beam evaporation (Bobeico *et al.*, 2003), etc.

As reported in our previous work, solid-state reaction between stoichiometric mixture of Cu_2O and Al_2O_3 at 1400K in air produced CuAlO_2 powder (Banerjee *et al.*, 2005b). This powder was then placed into a grooved aluminum holder ($\sim 5 \text{ cm}$ diameter) and pressed into pellets by hydrostatic pressure and used as target for dc-sputtering. The sputtering unit was evacuated by standard rotary-diffusion pump arrangement to a base pressure of 10^{-4} Pa . The target was arranged as an upper

Table 1 Summary of deposition parameters regarding dc-sputtering

Electrode distance	1.8 cm
Sputtering voltage	1.1 kV
Current density	10 mA cm ⁻²
Substrates	Si (4 0 0), glass
Sputtering gases	Ar and O ₂ (3:2 volume ratio)
Deposition pressure	0.2 mbar
Substrate temperature	453 K
Deposition time	4 h

electrode and negative bias was applied to it. Ultrasonically cleaned glass and Si substrates were placed on the lower electrode and connected to the ground of the power supply. The electrode distance was taken as 1.8 cm. Ar and O₂ (40 vol%) were taken as sputtering gas and the sputtering was done in an elevated substrate temperature (~ 453 K) to achieve high crystallinity in the film. Postdeposition annealing of the films (at 473 K) in an O₂ atmosphere (20 Pa pressure) for different annealing times (ta) ranging from 30 to 150 min were performed to induce nonstoichiometry in the films for enhancing p-type conductivity. Details of the deposition conditions were reported in other work (Yanagi *et al.*, 2000) and summarized here in the following Table 1.

The target was presputtered for 10 min to remove contamination, if any, from the surface and then the shutter was displaced to expose the substrates in the sputtering plasma. Si (4 0 0) and glass were used as substrates. Before placing into the deposition chamber, the glass substrates were cleaned first by mild soap solution, then washed thoroughly in deionized water and also in boiling water. Finally, they were ultrasonically cleaned in acetone for 15 min. Si substrates were immersed in 20% HF solution for 5 min for removing surface oxide layers. Then they were cleaned in deionized water and finally with alcohol in an ultrasonic cleaner. After the deposition was over, the films were postannealed in the same vacuum chamber at 473 K for 1 h (at pressure 0.2 mbar), maintaining the oxygen flow.

For the sol–gel synthesis the experimental is as follows (Ghosh *et al.*, 2009): copper nitrate, [Cu(NO₃)₂], aluminum nitrate [Al(NO₃)₃], and methanol (CH₃OH) were used as precursors for the material synthesis. In a typical run of experiment 7 mM of Cu(NO₃)₂ and Al(NO₃)₃ were stirred in 30 mL of methanol at room temperature for 45 min. This process was followed by addition of citric acid solution and the total solution was again stirred at room temperature for 1 h to obtain well-mixed precursor solution. When temperature was raised at 70°C with continuous stirring jellification of the solution got started after around two hours. The final products were obtained when the gels were heated at different temperature at several hundred degrees of temperature for six hours in open atmosphere.

The phase formation of the as-synthesized sample can clearly be understood from the X-ray diffraction pattern shown in Fig. 8. Fig. 9 shows the SEM image of a CuAlO₂ film deposited on Si substrate. It is seen that there is no particular structure that has been formed during the deposition. Only clustered type deposition has been taken place with irregular sizes. It is seen that the sizes of the small particles are beyond the limits of SEM resolution however bigger clusters are in the micrometer range, which is due to the higher formation temperature.

Fig. 9 XRD pattern of CuAlO₂ powder (a) and sputtered CuAlO₂ thin film deposited on Si (4 0 0) substrates and (b) SEM image of CuAlO₂ sol-gel powder sample synthesized at 1000°C for 6 h. Reproduced from (a) Banerjee, A.N., Kundoo, S., Chattopadhyay, K.K., 2003. Fig. 10 Seebeck coefficient vs. $1000/T$ of CuAlO₂ thin films.

Thermoelectric Properties of CuAlO₂

The performance of CuAlO₂ thin film, synthesized by dc sputtering, as thermoelectric material has been tested from room temperature (300K) to 550K. It is to be noted that postdeposition the thin films were annealed at 473K in oxygen atmosphere for different time (t_a), from 30 to 150 min. **Fig. 10** shows the temperature dependence of S for three types of films. It is seen that S is positive for all the samples, which confirms the p-type nature of the sample. It can be seen that the value of σ_{RT} comes out to be 230 $\mu\text{V K}^{-1}$ (for $t_a = 90$ min), 141 $\mu\text{V K}^{-1}$ (for $t_a = 60$ min), and 120 $\mu\text{V K}^{-1}$ (for $t_a = 30$ min). The figure shows that the value of Seebeck coefficient initially decreases from room temperature to around 390 K and then increases to almost 400 $\mu\text{V K}^{-1}$, for further increase in temperature. Also there are reports of the same material having values of σ_{RT} to be 183 and 214 $\mu\text{V K}^{-1}$ (Kawazoe *et al.*, 1997; Yanagi *et al.*, 2000), which are comparable to the values obtained in the author's laboratory.

Also there is a report from Koumoto *et al.* regarding the values of σ of CuAlO₂ single crystal as well as polycrystal at 600K around 180 and 150 $\mu\text{V K}^{-1}$, respectively (Akyildiz, 2015). A relatively high value of S_{RT} (670 $\mu\text{V K}^{-1}$) of CuAlO₂ powdered pellets has been reported by Benko and Koffyberg (1984). They have shown that σ_{RT} varies directly with conductivity of the sputtered deposited film, which shows consistency with the available Hicks model that predicts high ZT values of natural superlattice due to increase in both S and σ (Hicks and Dresselhaus, 1993).

It is to be noted that the structure of CuAlO₂ delafossite consists of alternative stacking of Cu^I and Al-O₆ octahedra edge shared AlO₂ layers. Here a c -axis oriented dumbbell shaped O-Cu-O bond gets formed due to coordination of one Cu atoms with two oxygen atoms. The O-Cu-O bonds all the Cu layers gets linked with all the AlO₂ layers (Ishiguro *et al.*, 1982). Thus a layered structure of CuAlO₂ gets formed where the charge carriers can more easily move in the two-dimensional ab plane than in the Al-O insulating layers.

Table 2 Different thermoelectric and electrical parameters of CuAlO₂ thin films, deposited at different annealing times

Sample	t_a (min)	σ_{RT} ($S\ cm^{-1}$)	S_{RT} ($\mu V\ K^{-1}$)	E_a (meV)	E_f (meV)
S1	90	0.39	+230	196	130
S2	60	0.16	+141	245	151
S3	30	0.09	+120	270	200

However, all this structural information cannot account for the efficient thermoelectric properties of the as-synthesized material. There are some proposed theories behind this phenomenon. Koumoto *et al.* (2001) predicts that low dimensionality of the crystal structure and the behavior of electrons and phonons in an anisotropic structural environment may be the reasons behind this. Also there is a report by Wang *et al.* (2003) that suggests spin entropy may be the reason for enhanced thermoelectric property seen in similar layered structured material like Na_xCo₂O₄. However it is still a subject of debate whether these reasons are responsible for the enhanced thermoelectric properties of layered CuAlO₂.

The variation of thermoelectric power (S) with temperature given by (Willardson and Beer, 1971):

$$P = \frac{k}{e} \left(A + \frac{\Delta E_f}{kT} \right) \quad (3)$$

$$\text{with } A = 5/2 - s \quad (4a)$$

$$\text{and } \tau = \tau_0 e^{-s} \quad (4b)$$

where k is the Boltzmann constant, e is the electronic charge, ΔE_f is the energy difference between Fermi level and the upper edge of the valence band, τ is the relaxation time for electron scattering, s is a constant that is different for different scattering mechanism, and τ_0 is a constant that is a function of temperature but independent of the electronic charge, e .

The above equation can be used to find the Fermi level from the plot between S and $1/T$, which comes out to be 130, 151, and 200 meV for $t_a = 90, 60$, and 30 min, respectively as obtained from Fig. 10, which is comparable to the value as reported by Benko and Koffyberg (1984) (190 meV).

Table 2 summarizes different electrical and thermoelectric parameters.

Fig. 11 represents the temperature dependence of thermoelectric power factor (σS^2) of CuAlO₂ thin film for the temperature range of 300–500K. The values come out to be $1.1 \times 10^{-7} \text{ W m}^{-1} \text{ K}^{-2}$ and $7.5 \times 10^{-5} \text{ W m}^{-1} \text{ K}^{-2}$ for the samples annealed for 30 and 90 min respectively, which is comparable to the previously reported values. Thus it can be concluded that the material CuAlO₂ may be a good candidate for use as thermoelectric material.

Table 3 summarizes the performance of different thermoelectric materials with respect to the figure of merit values

Conclusions

The worldwide energy crisis caused by increasing use of fossil fuel due to enhanced energy consumption and thereby generation of huge quantity of greenhouse gas like CO₂ is one of the most severe problems faced by human beings. The article discusses some aspects of the present energy crisis worldwide with possible solutions and also thereby mitigation of CO₂ emission. This problem is actually multifaceted and hence discussions on many other aspects are necessary. The different forms of alternative and renewable energies with their associated merits demerits have been discussed. Methods of waste heat energies are discussed in detail. The role of thermoelectricity in addressing the energy problems and associated CO₂ emission reduction is emphasized. The basic principles of thermoelectric effect and its corresponding theory have been discussed in detail. Materials aspects of efficient thermoelectricity generation are discussed and some published results are summarized. The features of some conventional thermoelectric materials are presented and the potential of a comparatively novel thermoelectric material, that is, copper aluminum oxide, has been presented. These discussions may be helpful particularly for the young researchers in this field.

Traditional Biomass: A Replacement for Petro-Fuels

Ranjana Das, Banashree Samanta, and Chiranjib Bhattacharjee, Jadavpur University, Kolkata, India

Introduction

Biomass is nothing but the plant or animal based material the main constituents of which are carbon, oxygen and hydrogen. Plant-based biomasses such as tree leaves, barks, stumps, and other parts are generally classified as lignocellulosic biomass. Biomasses are long being used since ancient time for heat and energy production during cooking and other general purposes worldwide. In recent time, the use of biomass is not only limited to cooking but also many processes have been developed to use it more economically such as production of biofuel in developed and developing countries all over the world. Different sources of traditional biomass (wood, eucalyptus, bamboo, *Jatropha curcas* (Raja *et al.*, 2011)); agricultural waste (sugarcane bagasse); industrial waste wastes (black liquor from pulp and paper industry; waste cooking oil, palm oil, soybean oil, sunflower oil, rapeseed and different vegetable oils, animal fat; algae; municipality solid waste) have already been reviewed. In recent few years, the scarcity of petro-fuels and the pollution originated from petro-fuels is an important topic of concern. Hence, the scientists are focusing on the production of clean energy sources and one of the main promising source of this type of energy is the biofuel which is comparable with those of conventional petroleum fuels with reduced emission of carbon monoxide (CO), carbon dioxide (CO₂), sulfur dioxide (SO₂), nitrogen oxides (NO_x) and other toxic gases and particulate matter (PM), unburned hydrocarbon thus resulting in reduction of Greenhouse Effect (GHE) and environmental pollution. A survey on Greenhouse Gases (GHGs) emission shows that 25% GHGs release throughout the world is caused by liquid fuels that are used in vehicles (Isa and Ganda, 2018). Another main problem with petro-fuels is their non-renewable nature and the continuous and rapid depletion of these fuel-reservoirs. Coal-gasification may be considered as an effective way to produce liquid petroleum range hydrocarbons but are not categorized as non-renewable source of energy. On the other hand, the use of fuel oil for mass transportation such as buses, cars, and ships, heavy duty engines in industries is increasing at fast pace. According to The United States Energy Information Administration report, the annual average increase in oil consumption was about 2.7% per annum in between 2009 and 2015 worldwide. Hence, a replacement of petro-fuels with some renewable energy resource appeals an urgent attention. In this case, biomass is a readily available renewable source of carbon mainly the lignocellulosic biomass as they are reproduced naturally by photosynthesis cycle. The main issue governing the biofuel production and commercialization has been reported as the discovery of novel procedure to produce biofuels that suits the economy of any nation. Based on the type of resource material biofuel are categorized as (i) first-generation biofuels (typically produced from food grade biomass like, starch, different type of waste vegetable oil). (ii) Second-generation biofuels (generally non-food biomass which mainly includes waste from agricultural farms), and (iii) third generation biofuel (algal biofuel) (Saladini *et al.*, 2016). In commercialization of biofuel the main factor is its source and in this case algae and palm oil have been proven to be very promising (Isa and Ganda, 2018). Lignocellulosic biomass having the propensity to produce transportation fuel as an alternative to petro-fuels (Addepally and Thulluri, 2015) hiking the popularity of bio based fuels and different state governments and federals are encouraging the production of biofuel. A contemporary survey report on production scenario of biodiesel in European countries prevails that its production rate is about 20–25 million gallon per year which is deviating to a large extent from expected production rate of 500 million to 1 billion per year (Gerpen, 2005). This exploration endorses the growing popularity of biofuel as an alternative to petro-fuels.

Traditional Biomass: An Unexplored Boon of Nature

Biomass is organic matter having wide spectrum of applications for both food and nonfood sectors. The harvested energy in the biomass has immense potential to be utilized as fuel resource. 'Traditional' or 'modern' biomass classification is based on the utilization over period of time. Traditional biomass refers the use of biomass that is long-established and is followed for centuries without any modifications, which mostly practiced in developing countries. Developed countries have recommended innovative idea for economic utilization of biomass such as for production of biogas (H₂, CH₄), liquid fuel, electricity generation and different type of fertilizer production. These activities have brought a breakthrough in the arena of energy research and developments and have endorsed traditional biomass to modern biomass. Sustainability of biomass is the key feature for exploiting it to energy production sectors. Studies have reported the complications associated in the sustainable biomass production processes (Anon, 2012) those are allied to availability of land for production and cultivation of biomass and environment suitability (Anon, 2012; Anon, 2012). Availability of land is directly or indirectly related with bioenergy generation. First generation biomass which are mainly the cultivated plants store about 1%–3% of solar energy by photosynthesis-process requiring a wide spread land area for fulfilling the energy demand of modern age. Hence the sustainability of biofuels greatly depends on sustainable land uses as replacement of natural vegetation with the cultivated one without affecting the eco-system. Oeko institute, Freiburg, Germany (2012) has calculated the 'minimum net energy requirement' for bioenergy carrier in details (Anon, 2012). Biodiversity is also considered as another important factor for sustainability of biomass. To ensure the sustainability of biomass, biofuel must be

Fig. 1 The global petroleum oil production scenario (<https://www.diva-portal.org/smash/get/diva2:476153/FULLTEXT01.pdf>).

confirming zero or close to zero emission of Greenhouse Gases (GHGs) and other pollutants (cause by disposal of the biofuel waste). Water & soil quality protection is also crucial factor during the cultivation of the biomass as energy stock.

Importance and Current Consumption Scenario of Petro-Fuels

Petroleum which is also known as 'Rock Oil' is a naturally occurring fossil fuel containing a wide range of hydrocarbons with different boiling point. Fuels are generally produced from this petroleum by refining this crude oil. After fractionation or distillation different liquid fuels are produced from this crude oil such as diesel, gasoline, kerosene, LPG, coal tar, naphtha, ethanol. This oil dominates the market in the area of road transportation and petrochemical industry as it has become one of the leading tradable commodities, but this oil source is finite and use of the petro-derived fuels have a negative effect on the environmental ecology, climate and is mainly responsible for Greenhouse Effect. Sulfur dioxide (SO_2) which is produced when petro-fuel containing sulfur is burned emits through different vehicles causes air pollution which is detrimental for human health. The production of petroleum oil worldwide is given by the Fig. 1 (see "Relevant Websites section"). The exploitation of oil globally was reported about 98.3 million barrels per day ($15,630,000 \text{ m}^3 \text{ d}^{-1}$) in the year of 2015 and estimated about 118 million barrels per day in upcoming year of 2030 (Energy Information Administration, 2006 prognosis). Since petroleum is unsustainable source of energy and hence exploration of alternative fuel sources have become crucial topic of research to energy sectors and environmental technologist. Though petroleum fuels are indispensable for community development but its scarcity and adverse environmental impact like global warming associated with emission of GHGs, acid rain, climate changing, and aquifer contamination, are highly threatening to the all kind of living beings and ecosystems. The present scenario about petroleum consumption presents a high rising of fuel price, making the fuel crisis protuberant and the necessity of alternative fuel as urgent and foremost crucial topic to maintain clean environmental.

Bio-Based Petro- Alternative-Fuels

Alternative fuels, are defined as non-conventional and advanced fuels, those are any materials other than conventional fuels like fossil fuels, nuclear materials as well as artificial radioisotope fuels those are used in nuclear reactors. Some of the most potential resources of alternative fuel explored till date and well recognized as alternative petroleum fuel are classified as biodiesel, bio alcohol, refuse derived fuel, fuel cells, hydrogen, non-fossil methane and natural gas vegetable oil though and abounded biomass resources are still waiting for exploration and recognition as alternative biofuel. The United States government has produced a 'data center' for the six most common alternatives of petroleum oil (biodiesel, bioethanol, hydrogen, natural gas, propane, electricity), summarizing the benefits and the challenges that still exist to bring them to a larger market.

Biodiesel

Bio diesel, resource material, production and utilization scenario

Biodiesel is a renewable fuel which can be made from vegetable oils, animal fats, or recycled restaurant grease. This can be used in diesel vehicles already on the road because of its similar fuel characteristics like petroleum diesel, but it burns much more cleanly and safely. It's totally biodegradable and friendly to the environment if spilled, but it has a flashpoint of over 130°C , compared to 52°C for normal diesel. Experimental studies have established that pure biodiesel (B100) reduces carbon dioxide emissions by more than 75% compared with normal diesel. The chemical nature of biodiesel is defined as mono-alkyl esters which can be produced from any potential lipid sources such as vegetable oil, animal fat or different type algal

biomass. Biodiesel is a promising renewable alternative fuel for conventional petro diesel. It reduces the carbon dioxide emission by 70%–75% in comparison with those conventional fossil fuels (Hillion *et al.*, 2003). The sulfur and nitrogen content of this fuel being less reduce the GHG emission and the toxic NO_x and SO_x with excellent lubrication efficiency. It entails little or no modification of the engine when it is used in place of petro diesel. This biodiesel can be used alone or can be blended with conventional diesel fuel to various recommended ratio to get various fuel grades. The most common are B5 (up to 5% biodiesel) and B20 (6%–20% biodiesel). B100 (pure biodiesel) is typically used as a blend stock to produce lower blends and is rarely used as a transportation fuel (see “Relevant Websites sections”). B20 is a common biodiesel blend used in the United States, because of its good balance of cost, emissions, cold-weather performance, materials compatibility, and ability to act as a solvent. Regulated fleets use biodiesel blends of 20% (B20) or higher qualify for biodiesel fuel use credits under the Energy Policy Act of 1992. Engines operating on B20 have similar fuel consumption, horsepower, and torque to engines running on petroleum diesel. B20 with 20% biodiesel content will have 1%–2% less energy per gallon than petroleum diesel, but most B20 users report no noticeable difference in performance or fuel economy. Many diesel engine original equipment manufacturers (OEMs) approve the use of B20.

Other high level biodiesel blends (B100) are less common than B20 and lower blends due to a lack of regulatory incentives and pricing. Biodiesel-compatible materials (as hoses and gaskets), allow B100 to be used in some engines built since 1994. B100 has good solvent effect, which help in cleaning vehicle's fuel system and releasing deposits accumulated from petroleum diesel use. The release of these deposits may initially clog filters and require frequent filter replacement in the first few tanks of high-level blends. While using high-level blends, a number of issue regulate its use is ‘energy value’ which is much less on a volumetric basis than petroleum diesel. Therefore, the higher the percentage of biodiesel (above 20%), the lower the energy content per gallon. High-level biodiesel blends impart negative aspect on engine performance, like gelling in cold temperatures. Some studies have reported that use of B100 could also increase nitrogen oxides emissions, requires special handling and require equipment modifications. Key features of the biodiesel for its well acceptability has been summarized as, its renewable, can be used in most diesel equipment with no or only minor modifications, can reduce global warming greenhouse gas emissions, compatible with new technology diesel engines (NTDE) and emissions control devices, can reduce tailpipe emissions from older vehicles, including air toxics, nontoxic, biodegradable, and suitable for sensitive environments, can be produced domestically from agricultural or recycled resources.

As presented in experimental research publications, the several potential raw materials for biodiesel production are waste cooking oil (WCO) (Raqeeb and R, 2015), animal fats (chicken or poultry fat, beef tallow and pork lard (Othman *et al.*, 2017)), waste vegetable oil (Refaat, 2010), Jatropha oil (Raja *et al.*, 2011), different types of vegetable oil such as soybean oil, palm oil, coconut oil, sunflower oil, algal biomass (Rawat *et al.*, 2013; Chisti, 2007; Kumar *et al.*, 2018), lipid containing waste slurry (Chena *et al.*, 2018).

The chemical method involve in the production of biodiesel has been classified as trans-esterification reaction of oil with alcohol in presence of catalyst. In literature trans-esterification process has been described as a simple reaction between triglyceride of any oil and fat material and low molecular weight alcohol such as methanol or ethanol (anhydrous or maximum water content of 2%) in presence of catalyst. The reaction stoichiometry has been presented in Fig. 2 (Hillion *et al.*, 2003).

The main advantage of methanol uses was reported due to ease of separation of the methyl ester by simple decantation process as compared to ethanolic derivative (Duarte *et al.*, 2007). Various catalyst system has been reported in literatures for efficient conversion of triglyceride oil and the fatty matter to respective methyl ester derivatives ranging from alkaline to acidic one, micro size to nano size and homogeneous to heterogeneous type. As typical homogeneous catalyst system sodium hydroxide (NaOH), potassium hydroxide (KOH) (Othman *et al.*, 2017; Nagi *et al.*, 2008), sodium methylate and many acid catalysts (Hillion *et al.*, 2003) have been attempted by eminent research groups. The system has significant drawback due to

low purity level of glycerol (80%–95%) (Hillion *et al.*, 2003) as byproduct because of the soap contamination in presence of moisture in reaction system. Hence, highly anhydrous (water content less than 1%) reaction condition has been recommended in few publications. Several acid catalysts like, strong sulfuric acid, hydrochloric acid, phosphoric acid and acids containing sulfonic group are typical with minimal chance of saponification reaction leading soap formation. The main restraint of the use of acidic catalyst system is the production of water as byproduct that constrains the yield of trans-esterification reaction (Marchetti *et al.*, 2007), requires high temperature ($> 100^\circ\text{C}$) and very slow reaction rate leading to few days of completion. Process efficiency has also been studied in details for the role of enzymatic catalyst (lipase) in trans-esterification reaction. Lipase catalyzed trans-esterification reactions require simple operational conditions compared to typical acid and alkali catalysts. The enzymatic catalyst was reported more effective with ethanol rather than methanol, the yield of ester is 75% for ethanol and only 15% for methanol when treated with PS30 lipase (Othman *et al.*, 2017; Enujiugha *et al.*, 2004). The deactivation and removal of catalyst system steps in homogeneous catalyst system have efficiently been eliminated by switching the method to heterogeneous catalyst system. A researchers' team has studied a heterogeneous catalyst system (consist of mixture of aluminum and zinc oxide) with rapeseed and soybean oil as raw material that requires high temperature of operation and excess methanol in comparison to the homogeneous system but gives a relatively pure, moisture free biodiesel product and recoverable alcohol system (Nage *et al.*, 2012).

At present scenario about 90% of biodiesel has been reported to produce by trans-esterification process of triglycerides with low molecular weight alcohols using homogenous acid or base catalysts. However, the biodiesel industries experiencing some significant challenges due to (i) high cost of biodiesel feedstock (70%–85% of the overall production cost) and (ii) cost of biodiesel processing, including separation, purification and neutralization of by-products. The use of nano catalyst in trans-esterification reaction offers comparatively high surface area and the catalyst displayed low catalytic activity for glycerin at reaction temperature. Moreover, the employments of heterogeneous catalysts offer easy separation from the products and reutilization facilities. Obadijah *et al.* (2012), have reported the use of Nano hydrotalcite (Mg-Al) for preparation of biodiesel from *Pongamia* oil with maximum conversion of about 90.8% for methanol to *Pongamia* oil molar ratio of 6.0, 1.5% catalyst (w/w of oil) for 4 h reaction time and an optimum temperature of 65°C . A number of researchers have studied the preparation of nano sized heterogeneous catalysts to increase the catalytic activity. Some important experimental works have been summarized in Table 1 demonstrating the significance of nano photo catalyst in trans-esterification reaction.

Algal lipid can also be used as resource of biodiesel production due to high triglyceride content. Some of the potential microalgae (freshwater) used for biodiesel production have been studied are *Cladophora*, *Enteromorpha*, *Mougeotia*, *Hydrodictyon*, *Oedogonium*, *Spirogyra*, *Microspora* (Kumar *et al.*, 2018), surface-floating microalga, such as *Botryo sphaerellusdetica* (Nage *et al.*, 2012). The schematic for production of algal biodiesel has been presented on Fig. 3. Though biodiesel can be used as fuel for the engines in place of conventional petro-fuel, but solely can't be utilized because of poor oxidation stability, lower calorific value and poor cetane index. It is usually blended with fossil fuel like, n-butanol in wide range ratio to get a better fuel quality (Kumar *et al.*, 2018).

Bio Hydrogen

Hydrogen is considered to be one of the cleanest sources of fuel which on burning it generally produces heat and clean water and it has high gravimetric energy density almost 143 MJ Kg^{-1} (Khan *et al.*, 2017) but low volumetric energy density nearly 12 MJ m^{-3} (at NTP) (Singh *et al.*, 2015). Electrolysis of water and steam reforming of water are the common methods for hydrogen gas production. Current world is in the phase of energy crisis due to extensive exploitation of fossil fuel reservoirs and rapid depletion of petroleum and others gas and solid fuel sources. One of the main disadvantages of this petroleum or other fossil fuels is the anthropogenic CO_2 emission and Greenhouse Effect. Bio hydrogen production is environmental friendly approach from the area of utilization of waste biomass to produce energy with minimal pollution emission.

Bio hydrogen resource material, production and utilization scenario

To solve the issue of energy crisis several group of researchers have explored different techniques to utilize waste biomass to produce petroleum alternative fuels. Different types of biomass can be used to produce bio hydrogen like, marine biomass (mainly

Fig. 3 The schematic presentation of algal biodiesel.

agar polysaccharide which mainly contains galactose) (Wu *et al.*, 2017), sugarcane bagasse (Hu *et al.*, 2018), agricultural residues, organic waste from industries (Lin *et al.*, 2018), sewage sludge, lignocellulosic biomass (Boodhun *et al.*, 2017), cheese whey waste (Patel *et al.*, 2016), Cow dung compost (Wu *et al.*, 2010), food waste (Moon *et al.*, 2015) etc. different biomass and organic wastes are treated in different methods to produce bio hydrogen.

Hydrogen/bio hydrogen are considered as future source of alternative fuel due to its salient features of non-polluting emission, high energy density and sustainability. As per recent reports, the amount of hydrogen production worldwide is about 700 billion N m^3 which solely depends on fossil fuel (Ball and Wietschel, 2009). This renewable source of fuel caters high energy yield (almost 122 kJ g^{-1}) compared to fossil hydrocarbon fuel (nearly 2.75 times higher) (Singh *et al.*, 2015). Current reports present that about 50 million ton of hydrogen is marketed per annum and with trade off growth rate of 10% annually (Winter, 2005). Various techniques and methodologies have been summarized (dark Fermentation, photo Fermentation, sequential dark and photo fermentation, combined dark and photo fermentation) in publications and further developments are under way to produce bio hydrogen as part of waste biomass utilization (Argun *et al.*, 2016).

The principle of dark fermentation is based on anaerobic process of hydrogen gas production and mainly produces a mixed gas which contains mainly hydrogen and carbon dioxide (Kim, 2003). The biomass feedstock for dark fermentation has been broadly classified in five groups such as simple sugar containing waste, starch containing waste, waste having cellulose content, waste from various food industry and waste water, bio solids or waste sludge (Kapdan and Kargi, 2006). Glucose, sucrose and lactose are the simple sugars from which bio hydrogen can be generated. H_2 yield per mol glucose is 4 mol with acetate while 2 mol H_2 per mol glucose with butyrate (Kapdan and Kargi, 2006). The reaction scheme has been summarized in Eqs. (1) and (2) (Kim, 2003).

A study has reported that the yield of hydrogen from sucrose is much higher about 4.52 mol H_2 per mol sucrose when operated in CSTR for 8 h hydraulic residence time (Chen and Lin, 2003) but another study by same researchers has been proved that the amount of hydrogen obtained for the same condition in CSTR is only 0.91 mol H_2 per mole glucose (Chen and Lin, 2000). In case of lactose a maximum of 3 mol H_2 can be obtained from 1 mol of lactose (Collet *et al.*, 2004). Researchers have concluded that bio hydrogen production was maximum for sugar waste containing sucrose. Starch which is another abundant source of substrate for

dark fermentation can yield 553 mL of hydrogen gas from 1 g of starch through acetate as intermediate (Zhang *et al.*, 2003). Cellulose which is available in plenty from agricultural waste, industrial waste such as paper and pulp industries, food industries is also capable of producing hydrogen under certain condition. It has been reported that for increasing concentration of cellulose the yield of bio hydrogen decreases (Kapdan and Kargi, 2006). Ample amount of carbohydrate was found in waste water coming from food processing industries, household activities, municipal sewers and solid wastes are rich in polysaccharides and protein hence having the potential to be utilized in hydrogen production with proper pathways. In dark fermentation process, several bacterial systems are involved like, aerobes (*Alcaligene* etc.), mainly anaerobes (bacteria belonging to genus *Clostridium*) and facultative anaerobes (*Enterobacter aerogenes*) (Kim, 2003). The temperature was maintained in different range depending on the nature of the bacterial systems utilized like mesophilic (25–40°C), thermophilic (40–65°C), extreme thermophilic (65–80°C) and hyperthermophilic (>80°C) (Kim, 2003; Levin *et al.*, 2004) under pH range of 6.5–7.5 (Boodhun *et al.*, 2017). The major challenges in bio hydrogen production are those have been identified as the selection of the potential resource material and the underlying pathways to be followed for the production as well as the microbial system selection. Side reactions such as methane and alcohol production are also responsible for low yield of hydrogen (Khan *et al.*, 2017).

Single stage photo fermentation has been reported in several other publications as bio hydrogen system method from polysaccharides. In this technique, waste stream containing polysaccharides cannot be directly used as feedstock hence was converted to monosaccharide prior to the treatment with photo fermentative bacteria. Some bacterial system has been reported to produce hydrogen gas from acids such as lactic, acetic and butyric, propionic, malic acids (which are produced during dark fermentation process) using wide spectra of light with CO₂ as a byproduct (Kapdan and Kargi, 2006). They are called photosynthetic bacteria and main type of such bacteria includes purple bacteria (non-sulfur) such *Rhodobacter capsulatus* (Kapdan and Kargi, 2006), *Rhodobacter sphaeroides* (Argun *et al.*, 2016). With this second bacterium, at a sugar concentration of 5 gL⁻¹, the yield of H₂ was 1.23 mol per mol glucose (Kapdan *et al.*, 2009). The production rate of hydrogen for this type of process greatly depends on composition of media such as concentration of Mo, Fe and other nutrients, pH, temperature.

In sequential dark and photo fermentation process, production was achieved in two stages of operation. The first stage organic acid substrate produced in dark fermentation process and then the photo fermentative bacteria culture is used to break down those organic acids to hydrogen and carbon dioxide in second stage. Same bacteria are used as for the single stage photo fermentation process. The optimum condition maintained for bio hydrogen production summarized as 30–35°C and 7 respectively (Kim *et al.*, 2006; Molino *et al.*, 2013).

The process schematic for the production of bio hydrogen utilizing wastes from agricultural farms and food industries as source of starch and cellulose has been presented in Fig. 4(a and b) (Kapdan and Kargi, 2006).

In combined dark and photo fermentation technique, production was achieved in single stage. In single reactor both the dark fermentative and photo fermentative microorganisms are cultured for the effective production of hydrogen. The first type of microorganism dissociates the complex carbohydrates into hydrogen and organic acids and then the second type of microorganism convert those acids into further hydrogen and carbon dioxide thus, inhibiting the accumulation of organic acids in the reactor. The main challenges of this method lie upon the conditions of the reactor such as temperature, pH, nutrient composition, intensity of the light source applied and so on.

Fig. 4 (a) The process schematic for the biohydrogen production steps utilizing wastes from agricultural farms and food industries; (b) schematic presentation of different biohydrogen production processes. Reproduced from Chandrasekhar, K., Lee, Y.-J., Lee, D.-W., 2015. Biohydrogen Production: Strategies to Improve Process Efficiency through Microbial Routes, International Journal of Molecular Sciences 16 (4), 8266–8293. Available at: [doi:10.3390/ijms1604826](https://doi.org/10.3390/ijms1604826).

Bio hydrogen is clean sustainable renewable energy supply that plays a key role in all sectors of the economy. The proper realization of the technological potential of hydrogen may be helpful in contributing sustainable growth of the world economy, a stable supply of energy with reduced future emissions of greenhouse gases. For H₂ to be renewable fuel it must come from renewable sources and bio hydrogen production need to be economically feasible. However, extensive research and technological developments are needed bio hydrogen production methods for commercialization.

Bio Methane

Methane is a nontoxic gas and it is generally lighter than air. Methane can be used as a powerful fuel as its net heating value is 11946 MJ kg⁻¹. Since methane is well recognized as greenhouse gas hence, from environmental safety issue control of its emission and effective utilization is appearing as emerging research topic with economic value.

Bio methane resource material, production and utilization scenario

Typical resource materials for bio methane production are characterized as organic matter with sufficient carbon content (Molino *et al.*, 2013). A wide range of organic matter such as fecal waste of animal and human being; food waste such as fruit peel (Pisutpaisal *et al.*, 2014), waste vegetable, crops and cereals (Negri *et al.*, 2014), domestic wastes such as leftover foods, industrial waste water, sewage waste have been already attempted as feed stock for bio methane production.

The method of production of methane from organic waste is the anaerobic digestion (AD) of biomass (Mishima *et al.*, 2006; Molino *et al.*, 2013; Moodley and Kana, 2017). Anaerobic digestion is generally a biological process with assistance of micro-organism to breakdown organic matter significantly in absence of oxygen or with little amount of oxygen. The end product of this process is generally methane containing biogas, hydrogen and solid sludge (Roati *et al.*, 2012). Three sequential steps namely hydrolysis, acidogenesis and methanogenesis comprise the anaerobic digestion process (Winter and Temper, 1987). The first stage hydrolysis is also known as liquefaction and in this step the microorganism reacts with the organic complex matters to break down them into simpler forms by secreting appropriate hydrolytic enzyme for the reactions. For lipid to fatty acid conversion enzyme secrete lipase enzyme, for protein to amino acid the secreted enzyme is amylase enzyme (Molino *et al.*, 2013). In acidogenesis stage, bacteria act on those simpler soluble organics which are the product of previous stage and gives volatile organic acids such as acetic acid, propionic acid, hydrogen and carbon dioxide, little amount of ammonia is sometime also produced depending on the feedstock composition. Ethanol is another important product during acidogenesis process. The bacteria involved in these steps are *Syntrophomonas wolfei*, *Clostridium spp.*, *Syntrophobacter uolinii* (Molino *et al.*, 2013). Third step is the methane production, bacteria facilitates the methane production from organic acid (such as CH₃COOH) or inorganic carbon dioxide and hydrogen (CO₂/H₂); these bacteria are called methanogens such as, *methano coccus*, *methano bacillus*, *methano sarcina*, *methano bacterium* (Molino *et al.*, 2013). This methanogenesis is an anaerobic process and oxygen acts as an inhibitor for action of the microorganism. The basic reaction stoichiometry is presented in Eqs. (4) and (5).

The final raw biogas obtained from anaerobic digestion not only contains methane but also contains different types of impurities such as moisture, hydrogen sulphide (H₂S), carbon dioxide (CO₂), ammonia, sulfuric acid etc. Biogas produced in this case contains roughly 60% methane (Vijay and Kapdi, 2006) and rest of the impurities mainly consists of carbon dioxide. Our motive should be to make methane rich biogas by removing the impurities as much as possible to increase the energy density of biomass, to reduce the corrosion and improve the efficiency of biogas system. H₂S is a hazardous gas for our health and environment as H₂S (in biogas) on burning produces SO₂ which in turn combines with water vapor to give sulfuric acid (H₂SO₄) causing corrosion of entire biogas system (such as pipeline, valve, vessels, reactors, regulators) and contamination of the material under use (Shah and Nagarseeth, 2015). CO₂ which is the major impurity of biogas is undesirable as it reduces the energy efficiency of biogas and causes environmental pollution. H₂S can be removed from the raw biogas by various ways such as addition of different metal oxide solution to the anaerobic digester to get nearly insoluble metal oxides; biological treatment such as sulphide oxidation by chemoautotrophic microorganisms mainly of species *Sulfolobus* and *Thiobacillus*; usual method of chemical treatment with caustic solution; utilization of adsorption technology (Ramaraj and Dussadee, 2015). Recently another novel technique has been come into play to purify the biogas to improve its calorific value by removing the impurities and increasing the methane concentration and this technique is the membrane processing. A special type of polymeric membrane that is very stable and durable towards the untreated biogas that contains ammonia, water, carbon dioxide, hydrogen sulphide and capable of giving almost 95% pure methane as retentate in a single run (Molino *et al.*, 2013). Hence biogas can be purified by both chemical and physical processes to get bio methane.

Bio methane can be used as a replacement for natural gas after its purification and can be used as fuel for transportation purpose instead of Compressed Natural Gas (CNG) or Liquid Natural Gas (LNG); it can be used as fuel for heat and power such as electricity production (see "Relevant Websites sections"). A typical bio methane production route with potential application pattern has been presented in Fig. 5.

Fig. 5 Process schematic of bio methane production route with potential application pattern. Reproduced from Wu, B., Zhang, X., Bao, Di., *et al.*, 2016. Biomethane production system: Energetic analysis of various scenarios. *Bioresource Technology* 206, 155–163.

Bio Alcohol

Bio methanol (CH_3OH), bioethanol ($\text{C}_2\text{H}_5\text{OH}$), bio propanol ($\text{C}_3\text{H}_7\text{OH}$) and bio butanol ($\text{C}_4\text{H}_9\text{OH}$) (Demirbas, 2008) are collectively known as bio alcohol among which most common and abundantly producible bio alcohol is the bioethanol and last two are less common from the area of production and utilization. Bio alcohols of two types first generation and second generation bio alcohol; in the production of first one human or animal consumable plant parts are used and in the generation of the second one non-edible parts of plants are used (see “Relevant Websites sections”). Bioethanol can replace the conventional gasoline in the transportation vehicles as its energy efficiency (heating value is 26.4 MJ kg^{-1}) is comparable to petrol and it produces less amount of CO and other pollutants after burning or can be mixed with gasoline because of its octane rating is high.

Bio alcohol resource material, production and utilization scenario

The main feedstock for bio alcohol production are bio crops for both first (starch and sugar plants) and second generation (grass, bagasse) bio alcohol; industrial waste such as waste from paper and pulp industries that contains ‘kraft lignin’ and liginosulfonates, agricultural waste such as lignocellulosic wastes, wet manure, oil crop wastes such as waste from coconut, olive, rapeseed oil plant (Kasmuri *et al.*, 2017).

Pretreatment of lignocellulosic biomass is always necessary before the main course of production. The main purpose of pretreatment of biomass is the fractionation of lignocellulose into different components such as lignin, cellulose, hemicellulose (Chen *et al.*, 2017) and to breakdown the bond between them to release sugar easily without or with less degradation of the sugar (Bhatia *et al.*, 2017). Generally, four different type of pretreatment can be done with the biomasses which are physical, chemical, physiochemical and biological (Bhatia *et al.*, 2017).

The main physical pretreatment method consists of washing of the biomass material to remove dust and dirt and then drying followed by grinding and screening. Grinding helps the starch or sugar containing part of any biomass to be free to interact and it also increases the surface area for reactions involved in the later steps. Microwave irradiation (Moodley and Kana, 2017) and sonication are other two pretreatment methods. Pyrolysis which is nothing but the exposure of biomass at high temperature without presence of oxygen can also be included as an effective pretreatment for the biomass.

Chemical treatment is the most widely used method of pretreatment. Chemical treatment is usually done to enhance the biodegradability of cellulose material by the removal of hemicellulose or lignin from it (Zheng *et al.*, 2009). The chemical pretreatment methods comprise acid treatment, alkali treatment, utilization of oxidizing and ionic liquids, ammonia treatment (Bhatia *et al.*, 2017; Zheng *et al.*, 2009). Acid or alkali treatments are sometimes performed for the rupture of the fibrous materials so that they can be easily accessible by the enzymes during hydrolysis (Elemikea *et al.*, 2015). Generally, two types of acid treatment are in use one is the concentrated acid treatment and another one is the dilute acid treatment. Concentrated inorganic acids such as HCl and H_2SO_4 (Vedernikov *et al.*, 1991) are generally used. Other acids such as per acetic acid (Zhao *et al.*, 2007), phosphoric acid (Israilides *et al.*, 1978), and nitric acid (Brink, 1993) are also used during dilute acid treatment. Alkali treatment is generally performed to solubilize hemicellulose, lignin and cellulose from biomass and it is also capable of removing acetyl and

Table 2 Advantage and disadvantages of sustainable petroleum alternative fuels

Advantage	Disadvantage
Biohydrogen: Biohydrogen is a clean source of energy having higher energy density and environmental friendly as there is zero emission of GHGs when it is used as fuel in fuel cell (Argun <i>et al.</i>, 2016) and during its production less amount of chemicals are required as it is produced by microorganism. Conventional production methods such as steam reforming of methane, other hydrocarbon requires very high energy during operation ($>850^{\circ}\text{C}$) whereas biohydrogen can be produced around 24h by dark fermentation and less energy intensive. One of the main advantages of biohydrogen production is that a wide range of biomass feedstock of low cost (Anon) can be used in dark fermentation and being an anaerobic process it does not claim oxygen during reactions (Vijay and Kapdi, 2006). Biohydrogen can be produced by photo fermentation which when combined with dark fermentation process yields higher hydrogen productivity (Vijay and Kapdi, 2006).	Oxygen acts an inhibitor for fermentation process. During combined and sequential fermentation process continuous light is necessary for smooth operation; maintaining of this condition is very difficult when it is used in large industrial scale (Anon). The yield of hydrogen by fermentation process is very low and the resulting hydrogen gas contains many impurities such as CO_2 etc hence post treatment is a mandatory operation (Argun <i>et al.</i>, 2016; Vijay and Kapdi, 2006). –
Bio methane: Bio methane is considered to carbon neutral source of energy and as it is generally produced by biological method (Anaerobic Digestion) by means of microorganism, it is environmental friendly (nonpolluting and reduces GHG) and requires very less energy to be produced hence very much energy efficient (Azwar <i>et al.</i>, 2014). It is a renewable source of energy as waste biomass produced from living being is the feedstock for this bio methane aka biogas production.	Industrialization is one of the main constraints in the advancement of the bio methane production. Large scale production of bio methane is still requiring improvements. Many technologies must be developed and improved in order to make this energy cost effective.
Capital investment in the bio methane production is very insignificant compared to the profit acquired (Pandu and Joseph, 2012).	Another big limitation of bio methane production is its level of impurity. As raw untreated bio methane contains H_2S, H_2O, CO_2 and many other impurities hence its purification needs modern equipment and assembly and thus adds another cost to the production cost. Bio methane is very liable to suffer from oxidation when exposed to air or any other oxidizing medium hence unstable in nature and some can cause serious problem like explosion (Li <i>et al.</i>, 2017).
Bio alcohol: Bio alcohol is a renewable source of energy; carbon neutral and it reduces the environmental pollution and emission of Greenhouse Gases when blended to conventional gasoline in various ratios. The product (exhaust gases) of combustion of ethanol is purer as it undergoes complete combustion during burning. As the fuel is nontoxic and biodegradable accidental spills will not cause any considerable environmental hazards. Bio alcohol production is economic as it gives valuable side products during its preparation which could be profitable (Garba <i>et al.</i>, 1996).	Bio crops cultivation for bioethanol production is expensive and may cause scarcity of food. Proper knowledge for the optimum production of bio alcohol is required and capital cost laboratory set up is quite high (Ganiyu, 2005). –
Biodiesel: Biodiesel is nontoxic, biodegradable that means does not make accumulation in land or water if exposed (Sitepu <i>et al.</i>, 2014). Upon combustion biodiesel does not emit sulfur compounds, carbon mono or di oxides, polyaromatics thus subscribe to the minimization of global warming and environmental pollution (Komonkiat and Cheirsilp, 2013). Biodiesel has higher cetane number hence ignites fast and more completely which ensures the smooth performance of compression ignition engine (diesel engine) and reduces the extent of harmful gases generated by inadequate combustion reaction. For biodiesel application modification of engine is not necessary (Othman <i>et al.</i>, 2017). As biodiesel is dense oil it provides proper and apposite amount of lubrication to the engine parts. As it possesses indistinguishable properties like conventional fossil fuels and hence can be blended with them or can be used unassisted (Nagi <i>et al.</i>, 2008).	As the origin of feedstock for biodiesel production varies from country to country and type to type hence the petro-chemical properties thus the exhaust gas composition is not homogeneous (Othman <i>et al.</i>, 2017). The cost of production of biodiesel is higher and it is one and half time higher than the fossil diesel. Vehicles using biodiesel as the energy source requires perennial change of filter of the engine (Firoz, 2017). –

different uronic acid groups resulting in enhanced accessibility of enzyme towards cellulose or hemicellulose (Chang and Holtzapple, 2000). Chemicals used for this purpose are sodium hydroxide (NaOH) (Abdi *et al.*, 2000), potassium hydroxide (KOH) (Chang and Holtzapple, 2000), calcium hydroxide [$\text{Ca}(\text{OH})_2$] (Kim and Holtzapple, 2005), ammonium hydroxides (NH_4OH) (Prior and Day, 2008). Hydrogen peroxide (H_2O_2) (Mishima *et al.*, 2006) and ozone (O_3) (Maurya *et al.*, 2015) which

Fig. 6 Research scenario of the combined production of hydrogen and methane (biohythane). Lin, C-Y., Nguyen, T. M-L., Chu, C-Y., Leu, H-J., Lay, C-H., 2018. Fermentative biohydrogen production and its byproducts: A mini review of current technology developments. *Renewable and Sustainable Energy Reviews* 82, 4215–4220.

are oxidizing agents can also modify the biomass structure. Ionic liquids are “green” novel solvents that cater a high solubility and extraction of cellulose and with this it is almost possible to recover 100% of the solvent (Zheng *et al.*, 2009). Examples of ionic liquids include N-methylmorpholine-N-oxide monohydrate (NMMO), 1-ethyl-3-methylimidazolium [EMIM], 1-allyl-3-methylimidazolium chloride (AMIMCl) (Prashant, 2015).

Physiochemical processes of pretreatment of biomass include catalyzed steam explosion, ammonia fiber/freeze explosion (AFEX) etc. In catalyzed steam explosion some catalyst such as SO_2 , H_2SO_4 are reacted with biomass before the conventional steam explosion which offers additional advantages of steam explosion method (Zheng *et al.*, 2009). The mechanism of AFEX is that biomass is treated with hot ammonia under high pressure for a certain period of time and after it a sudden release in the pressure takes place causing decrystallization of cellulose structure and improved enzyme activity and digestibility towards it (Agbor *et al.*, 2011). One other physicochemical pretreatment of biomass can be the combination of steam with hydrogen peroxide (Verardi *et al.*, 2018).

As the name suggest biological method of pretreatment is more environment friendly compared to those chemical or physical methods. Both fungi (soft rot, white rot, brown rot) and bacteria are involved in this biological treatment. Among these microorganisms soft and brown rot fungi are more effective for disruption of cellulose while white rot fungi (*Cyathus stercolerus*, *Ceriporia lacerate*, *Phanerochaete chrysosporium*) are more prone to attack the lignin in the biomass (Mauya *et al.*, 2015; Schurz, 1978).

After hydrolysis of the biomass material the next step is the saccharification to produce reduced sugar. This is an important step in ethanol production. According to a recent study amyloglucosidase is used at pH 4.6 and with a temperature 50–60°C for 2 h for this saccharification purpose (Elemikea *et al.*, 2015). Next important step in ethanol production is fermentation by *Saccharomyces cerevisiae* yeast followed by distillation (Mushimiyimana and Tallapragada, 2016). As ethanol forms an azeotrope with water during distillation the distillation is generally extractive distillation and in this process the extracting solvent are generally cyclohexane, heptane, and benzene (Sarkar *et al.*, 2012). Bio methanol can be produced by fermentation and can be recovered by distillation as it does not produce azeotrope with water in the mixture (Voloshin *et al.*, 2016), by oxidation of carbohydrate in biomass aided by water and oxygen (Demirbas, 2009). Butanol is another alcohol produced during fermentation and in this process of fermentation *Clostridium spp.* is very much effective and a study reveals that approximate 14.4 g L⁻¹ of butanol can be possible with this conditions (Komonkiat and Cheirsilp, 2013). Bio butanol is a very promising renewable source of future world as it possesses energy content which is comparable with gasoline and it can be directly be applied in the engine as a replacement for petrol. Its octane number is also nearly equal to gasoline. Its handling is very comfortable as compared to bioethanol as it offers very low vapor pressure (Szulczyk, 2010; Jin *et al.*, 2011). Bio propanol is less popular bio alcohol and limited research works are involved with this fuel. Bio alcohol can be used as the fuel for gasoline engine or can be mixed to various ratios with gasoline to make transportation fuel. Bioethanol may be used to produce biodiesel by required processing.

Advantages and Disadvantages of Biofuel as a Replacement for Petro-Fuel

Since the term “biofuel” first entered the energy lexicon of the average consumer, there has been a steady stream of advancements to this technology. While general perceptions on biofuels may have changed over the years, quite a lot of interest in the pros and cons of this fuel source still remain. It is important for all to seriously consider both the positive and negative aspects of this

still-emerging technology. This section aims to briefly summarize all the pros and cons associated with the various alternative fuels commercially available and under exploration. The advantages and disadvantages are summarized in Table 2.

Future Prospect

Bio hydrogen, bio methane, bio alcohol, biodiesel all are sustainable and renewable source of energy of the future world providing a clean environment to all living being. Different associations and committees have been established to find out the regular and continuous inventions and development regarding these green energy technologies; such associations include Asia Bio-HyLinks (ABHL) [established in 2006] and APEC Research Center for Advanced Bio hydrogen Technology (ACABT) [established in 2009] for Asian countries. They arrange different events to explore the current pattern of research technologies available for bio hydrogen and bio methane energy efficiency (Schievano *et al.*, 2014). This combined production of hydrogen and methane via two stage fermentation is immensely famous as “biohythane” (Sen *et al.*, 2016). The research work regarding “biohythane” is increasing gradually and Fig. 6 (Boodhun *et al.*, 2017) shows this increasing trend. Though cost of raw material for bio hydrogen production is slightly high, biological way many dark and photo fermentation processes are most promising way of bio hydrogen production. The efficiency and yield of dark fermentation is low and it is considered to be one of the slowest process but when combined with photo fermentation it gives high hydrogen yield and lower the cost, time, energy expenditure; and all these is possible only by the utilization of optimum parameter conditions such as temperature, pH, biomass concentration (C/N ratio), microorganism utilization, hydraulic retention time (HRT) (Boodhun *et al.*, 2017; Kapdan and Kargi, 2006). Bio hydrogen production commercialization is a great constraint towards the development of industry regarding it. The global production rate of hydrogen per annum is around 50 million metric tons in which bio hydrogen or in turn hydrogen from biomass or renewable source accounts only 3%–4% and remaining from fossil raw material sources such as coal (19%–20%) and natural gas and naphtha (76%–77%) (Bakkenne *et al.*, 2016). From a current economic assessment, it has been come to know that the cost of hydrogen production by biomass gasification is USD\$ 4.60–7.86 per kg of H₂ produced (Dowaki *et al.*, 2007) and by pyrolysis it accounts USD\$ 1.3–2.2 per kg of H₂ produced (Khan *et al.*, 2017). Furthermore, a study shows that the cost of bio hydrogen production by dark fermentation processes with a 95 m³ photo-bioreactor was estimated to USD\$ 2.74 per kg H₂ when lignocellulogic material was its main raw material (Ljunggren and Zacchi, 2010). Different experts performed different benefit-cost ratio for this biohydrogen to check out its feasibility in large scale and one such result gives the ratio values for three different plants 3.85, 3.37 and 2.20 (Lee, 2016) which shows a satisfactory result.

Anaerobic digestion which is the main production procedure of biomethane has now improved by integration with other processes. One study shows that anaerobic digestion (AD) with upgrading gives 62%–64% bio methane production efficiency whereas gasification coupled with methanation which is also known as Göteborg biomass gasification project (GoBiGas) gives 65% efficiency which are nearly equal (Li *et al.*, 2017). Another study also shows that combination instead of competition will yield better result where anaerobic digestion gives an efficiency of bio methane production of 52% only when operated alone and this efficiency increases to a value of 67% when it is integrated with pyrolysis which gives 1.2 volumetric increase in the resulting bio methane (Salman *et al.*, 2017). While carrying out the economic analysis of this coupled process it prevails that the process is economically profitable and delivers a payback period of approximately six years with an annual rate of return of 16.5%. The presence of different studies and research works regarding bio methane production give the evidence for blooming future of bio methane. An observation of a research team compares the potential of various cereal crops for bio methane production; in their work they took two different kind of crops one is the single crop (maize only) and another one is the double crops (maize along with winter cereals) (Negri *et al.*, 2014). In their study they studied five different maize hybrid classes (300, 400, 500, 600, and 700); among them bio methane yield per hectare was highest for classes 600 and 700 and the among the winter crops triticale shows much liability than wheat. In our current stage of civilization second generation biofuels are more desirable for the healthy balance of the environment through eradication of food scarcity and proper management of bio waste materials. Such a work of second generation bio hydrogen and bio methane production was carried out by a research team where they use three types of waste material under study namely a blend of waste vegetable materials referred as “Mix”; ACV15, an un matured compost sample; and three different kinds of green composts to be specific ACV1, ACV2 and ACV3 (Arizzi *et al.*, 2016). All these studies show that bio methane is an attractive source of renewable energy and all we need it is proper industrialization for the future energy crisis concerns.

Bio alcohol which is another sustainable biofuel suffers from many drawbacks from different sectors mainly economic and social zones. Bio alcohol production will be profitable and will offer economic return if we bother with the side products during its production which are valuable (Hassan and Kalam, 2013). Bio methanol is an important bio alcohol but the production of bio methanol has some limitations. According to a recent study the feedstock for the bio methanol production such as corncob or sugarcane bagasse should contain less moisture generally less than 10% to get a higher yield; again the real conversion is very low such as 0.67% and 5.93% respectively; hence it requires large amount of biomass for effective commercialization (Shamsul *et al.*, 2014). Another study shows that Cassava cellulosic waste gives a yield of 2.7 g ethanol/15 g waste (32.4% alcohol) which is very low but can be improved if this second generation bioethanol process can be combined with the first generation technique which will satisfy the economic value (Elemikea *et al.*, 2015). As the first generation bio alcohol production is not warrantable hence more and more pressure is given on second generation bio alcohol production. Bioethanol is generally used as E10 grade where

there is 90% gasoline and 10% bioethanol present in the blend. The cost of bioethanol is also profitable; which was \$ 80 per barrel in November 2007 (Sen *et al.*, 2016). Hence bio alcohol can be treated as a promising clean fuel of future.

Different research works are continuously taking active participation in the refinement of the biodiesel production day by day. One such work shows that algal biomass accommodated from a river having fresh water which has low lipid content of 18.6% gives fatty acid methyl ester (FAME) whose characteristics are similar to those conventional fossil diesel (Kumar *et al.*, 2018). This biodiesel gives low carbon dioxide (CO₂) and nitrogen oxides (NO_x) in the exhaust gas when blended with butanol and conventional diesel and applied in a four stroke four-cylinder diesel engine. A research team conducted another interesting work on the biodiesel where they used waste cooking oil (WCO) on to which yeast *Yarrowia lipolytica* was made to be grown (Katre *et al.*, 2018). This experiment showed by means of a Plackett-Burman statistical design this biomass *Yarrowia lipolytica* was the key strand for the FAME production. Keeping all variable constant, with the increase of the biomass loaded the rate of production of FAME increases like 4 g of biomass applied yields 0.88 g of FAME in 8 h keeping all variable at a specific condition. This is a very prospecting work to be considered. Photo bioreactor is utilized all around there in the world for biodiesel production but an extraordinary photo bioreactor was developed by a research team to accelerate the rate of production of algal biodiesel (Pham *et al.*, 2017). In this work three different type of bioreactor were designed X-Shape, H-Shape, and serial-column among which X-Shape delivers most optimistic characteristics. Biomass and lipid production obtained for X-Shape photo bioreactor were 30.05% ($1.359 \pm 0.007 \text{ g L}^{-1}$) and 23.49% ($117.624 \pm 3.522 \text{ mg L}^{-1}$) more than those from the control photo bioreactor respectively. Thus the process shows that this can be accepted industrially for the production of biodiesel in future effectively. Many other trending inventions are present regarding the commercialization of biodiesel which proves a luminous future of this sustainable clean fuel.

Conclusion

As this article epitomizes, the potential of biofuel as an alternative of petro-fuel as an efficient path for sustainable fuel economy. The concern arising from the depleting availability of the petroleum and environmental issues have driven scientists and researchers to explore alternative fuel resources with development of green energy-economy system. Biomass being renewable matter have drawn surveillance of the researchers for exploration of its potential. Though woody fuels or plant based fuels have been cultivated mostly for fuel applications, as mentioned in major sections of this article but other alternative biomass resources are also emerging as potential resources for fuel applications like, animal wastes and municipal solid waste (MSW). In connection to the challenges arising from effective management of the increasing amount of produced municipal solid wastes and remediation of environmental hazard issue in concurrence to energy crisis issue, MSW can be the ultimate solution. The approaches to turn waste to energy have gained ground as methods for waste management. Both biological and thermochemical conversions of conventional plant based biomass and nonconventional MSW has been conducted in the last few decades to improved yield of product or energy formation together with decreased environmental impact. Presently, the society is facing a serious challenge for the effective alternative fuel with reasonable price value and economy of the biofuel has become the critical issue to address this connection. Economics of the biomass based fuel are strongly associated with fuel supply, including the total quantities available, the stability of the supply or of the industry generating the fuel, competitive uses and markets for the fuel. The low energy density of biofuel with cost of fuel collection and transportation can outweigh the value of the fuel hence, economy of the fuel is pivoted on the precise selection of the biomass. So, biomass need conservation and through scrutiny for societal wellness.

An Ultra Low Power Molecular Quantum Dot Cellular Automata Based X-ray (QX-ray) Generating System Using Renewable Energy Source

Paramartha Dutta, Visva-Bharati University, Santiniketan, India

Debarka Mukhopadhyay, Adamas University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Industrial revolution that got full swing in the 19th century initiated use of increasing amount of fossil fuels such as coal, oil, gasoline, natural gas etc.

Power station generates power by combustion of fossil fuels. These non renewable energy source generates gases like CO_2 , CH_4 etc., which are greenhouse gases. With higher concentration of CO_2 and CH_4 in the atmosphere the infrared radiation from earth is not able to find free passage through Oxygen and Nitrogen, the major transparent ingredient of atmosphere. Solar radiation mostly in the form of visible light causes generation of heat while absorbed into the earth surface. This heat is radiated as infrared radiation. This infrared radiation gets absorbed by these greenhouse gases and does not get easy passage into space. This absorbed heat causes global warming.

Use of sources of green energy or clean energy may be the future solution for global warming. The energy is derived from natural processes that do not radiate greenhouse gases and replenished also by nature. This energy is derived from various natural sources such as sunlight, wind, rain and tides. It can replace fossil fuels in almost all major areas of utilization.

The most common source of renewable energy is solar power. Photovoltaic cells produce solar power capturing sunlight turning subsequently into electricity. After commercialization, this technology has become inexpensive and utilized in daily needs.

Air flow through surface is another source of renewable energy that pushes turbines and generates power.

Hydroelectric power may be generated through earth's water cycle, rainfall, force of water running through a dam etc.

Our current contribution here is to propose a methodology that enables us avoiding combustion of non-renewable energy such as fossil fuels and using power through renewable energy source such as sunlight to run Quantum Dot Cellular Automata based X-ray generating system.

The use of sunlight as energy source enables us to avoid the application of huge amount of voltage and consumption of huge power and energy in existing technology. The Quantum Dot Cellular Automata paradigm reveals a methodology that requires the application of small amount of voltage and consumption of less amount of energy and power as compared to existing technology to radiate X ray with same intensity.

The existing digital X ray needs the use of approximately 80 kV of voltage and 80 kW of power whereas the proposed X ray system needs application of voltage in the range of 2–2.81 V_{rms} and power in the range of watt only. So, proposed methodology ensures power generation through renewable energy source, debarring the use of sources of greenhouse gases and radiates X ray with minimum application of voltage and power.

One of the biggest discovery in the 19th century was the discovery of X-ray by Wilhelm Röntgen. That time it was an unknown type of radiation and termed as X-radiation or X-ray. The existing convention for production of X-ray requires X-ray tube. It is a vacuum tube that employs a high voltage (see "Relevant Website section") to accelerate the electrons released by a hot cathode plate. These high velocity electrons colliding with metal anode radiate X-rays. While colliding with anode, electrons knock an orbital electron out of inner electron shell of anode atom. The electrons from higher energy level then fill up the vacancy and radiate X-ray. The existing process of generating X-ray is inefficient with production efficiency of only one percent (Jerrold *et al.*, 2002; Camara *et al.*, 2008). The process encompasses good amount of power to produce the required flux of X-ray. Digital X-ray generator employs 440 VAC, 50/60 Hz supply with three to single phase transformer. Here around 80 kVA amount of power is generated during the process of X-ray generation. Most of this amount is lost and consumed by the tube as waste heat. The existing X-ray tube is designed in such a way that it can dissipate the excess heat. Energy and power loss are big concerns while generating X-ray and plenty of research efforts are going on around the globe. Around 2500°C of temperature is generated in the existing process imperatively requiring associated cooling system. Quantum dot Cellular Automata (Lent, 1997) paradigm can be employed to generate X-ray wave with very less amount of supply voltage in the range of 2–2.81 V_{rms} and very small amount of power consumption in the range of watt only.

This is worth saying that a mathematically monotonic relation seem prevalent while relating voltage consumption and power consumption with generation of greenhouse gas. But to the best of our knowledge, there is hardly any established equation relating this three parameters. As such any device with lesser power/energy requirement is more desirable from the perspective of greenhouse effect. Less the power/energy consumption, is the more environment friendly the device would be. This is primarily because the major source of energy is combustion of fossil fuel and carbon source. in the present day scenario. Accordingly a low power device based on nano-technology stands in good stead from environmental point of view. Our present proposal appears meritorious in this context.

We will analyze first the technical feasibility of fabrication of metal dot QCA using electrometer. Accordingly, we ascertain whether it is possible to achieve the same at room temperature. The study in the next three sections establishes that the radius of graphene based metal dot will be in attometer dimension only which is not possible to fabricate in respect of available technology.

The present invention (Roy *et al.*, 2018, 2017) relates to Molecular Quantum Dot Cellular Automata methodology for generating X-ray wave from QCA unit.

Consideration of SET to Determine the Radius of Island of Metal Dot QCA

4 Dot 2 electron metal dot QCA is fabricated using single electron transistor due to associated advantages like small size, low power consumption, and ability to perform fast and sensitive charge measurements (Devoret and Schoelkopf, 2000). Fig. 1 (Snider *et al.*, 1999) depicts the schematic of the metal dot QCA realization. Fig. 2 (Durrani and Ahmed, 2008) indicates SET circuit which comprises a dot between the Source and Drain electrodes. The island is separated from these electrodes by a tunnel junction. Each tunnel junction has its resistance and capacitance as shown in Fig. 3. The dot is also capacitively coupled to the Gate electrode which also has a capacitance to control current flow. The total capacitance (C) between the dot and outer environment is given below:

$$C = C_1 + C_2 + C_g \quad (1)$$

Fig. 1 Simplified schematic of the four-dot QCA cell and electrometers.

Fig. 2 Single electron transistor.

Fig. 3 Tunnel junction.

Fig. 4 The drain-source current, I_{ds} , V_s the source-drain voltage, V_{ds} , characteristics of this system in the presence of single electron charging effects (solid line) and in the absence of single electron charging effects (dashed line).

Fig. 5 The stability charge diagram of the source-drain voltage, V_{ds} , across a SET as a function of the gate voltage V_g . The gray regions have zero source-drain currents I_{ds} (Coulomb blockade regions).

C_1 , C_2 and C_g denote drain capacitor, source capacitor and gate capacitor respectively. Three conditions need to be met to achieve coulomb blockade.

$$(1) V_{bias} < \frac{e}{C}$$

Here V_{bias} denotes bias voltage, e denotes elementary charge and C denotes total capacitance.

$$(2) R_t > \frac{\hbar}{2\pi e^2}$$

Here R_t denotes the tunneling resistance and $\hbar$ is plank's constant. This condition is derived from Heisenberg's uncertainty principle.

$$(3) KT < \frac{e^2}{2C}$$

Here KT denotes the thermal energy, $K = 1.3806505 \times 10^{-23}$ joules/kelvin, $\frac{e^2}{2C}$ denotes the charging energy or coulomb energy. If this condition is not met then the electron will pass the quantum dot via thermal excitation. When one electron overcomes the charging energy and tunnels into the quantum system, it blocks the tunneling of a second one since it would charge additionally the quantum system by an amount $< \frac{e^2}{2C}$. The effect is that a single electron may tunnel through at a time.

In **Fig. 4** the region $-\frac{e}{2C} < V_{dc} < \frac{e}{2C}$ is called coulomb blockade region, with a coulomb gap voltage V_{gap} . In this region the electron's energy is smaller than the repulsive Coulomb energy of the electrons on the island as shown in **Fig. 5**.

Determining the Radius of Island in Room Temperature

In SET the island can be explained by assuming a small metallic sphere, as shown in **Fig. 6**. This island is initially electro-neutral i.e., the net charge on this island is zero since the number of electrons and protons are same in it. Now, consider that a single electron is placed close to the island. In this situation, it gets attracted by the island. Thus, this single electron comes into the island and leaves a negative charge of e on it. Now, due to the presence of this negative charge, an electric field is created around the island so that in the event of another electron approaching close to this island, it will face a strong repulsive force induced by the electric field created around the island (Sinha and Sanjay, 2014). The total capacitance(C) corresponds to the self capacitance of island. When the island is a sphere with a radius of R embedded in a dielectric material with a dielectric constant, the self capacitance (Weis, 2004; Gupta, 2016) is given by

Fig. 6 (a) An electron feeling a small attractive force as it approaches a sphere. (b) Once sphere gets charged negatively by a single electron; other electrons will feel a strong repelling force.

$$C_{self} = 4\pi\epsilon_0\epsilon_r R \quad (2)$$

Where ϵ_0 and ϵ_r are permittivity of free space and permittivity of dielectric material of capacitor. From the 3rd condition we get $C < \frac{e^2}{2kT}$. Therefore at room temperature (300° kelvin) $C < 3.09 \times 10^{-18} F$.

Here we use graphene as a metal of island as graphene is a good conductor. In the 5–40 GHz range encompassing the microwave and the lower part of millimeter wave spectrum, the electrical permittivity of graphene is almost 3 (Cismaru *et al.*, 2013). This experiment was carried out using a coupled co planar wave guide placed over a graphene mono layer flake, which is deposited on Si/SiO₂. So the relative permittivity of graphene is 3.3882×10^{11} . Now from Eq. (2) we can write,

$$4\pi\epsilon_0\epsilon_r R < 3.09 \times 10^{-18} F \quad (3)$$

Thus, $R < 0.819721$ Auttometer

Here we performed studies for the radius of island in room temperature. It is seen from Eq. (3) that the radius of island will be in auttometer range which is not possible to fabricate using graphene as a metal.

QCA Cell and Molecular Cell Clocking Arrangement

The QCA cell and electromagnetic clock signal are the most vital ingredients in the invention of X-rays radiated from QCA cells which consume very less amount of electric energy and power.

QCA Cell

Each cell is composed of two V shaped molecular structures and has six redox sites. as shown in Fig. 7. The redox sites are considered as quantum dots. The figure depicts three stable configurations of the two mobile electrons within the molecular cell. Mobile electrons establishing themselves at the upper diagonal sites (i.e., either at cites 2 and 0 or 1 and 3) represent ACTIVE states of the cell. These active states carry two polarities of the cells viz. $P = \pm 1$. $P = 1$ is said to represent binary '1' and $P = -1$ represents binary '0'. When the two mobile electrons are positioned at the two sites depicted below, the cell is said to represent 'NULL' state. Fig. 8 indicates molecular cell dimension. Here we employ cell size (d) to be 1 nm and height (h) to be 1 nm (Lu *et al.*, 2006; Lu *et al.*, 2007).

Molecular System Clocking Arrangement

Clock signal is applied through submerged electrodes buried in oxide layer (Karim *et al.*, 2010).

Managing Electrodes

The electrodes carry electromagnetic clock signals and they are placed at the bottom of the oxide layer. The phase shifted sinusoidal signal is applied to each of the electrodes to energize the electrons. Fig. 9 depicts the four phases of the applied sinusoidal signal viz. ϕ_1, ϕ_2, ϕ_3 and ϕ_4 with $\phi_1 < \phi_2 < \phi_3 < \phi_4$ such that the data may flow in the direction as indicated in Fig. 9. This electric field $\vec{E}$ in the Y and $-Y$ directions switch the molecular cell from ACTIVE state to NULL state and vice-versa. The electrodes have finite radius and potential voltage is applied with respect to grounded plate as per Fig. 11. Average electrode potential (Karim *et al.*, 2010) is determined as,

$$V_{avg} = \frac{V_{e1} + V_{e2}}{2} \quad (4)$$

where V_{e1} and V_{e2} are the potentials on two adjacent electrodes. The electrode potential difference between these two adjacent electrodes can be given as,

$$\Delta V_e = |V_{e2} - V_{e1}| \quad (5)$$

Fig. 7 QCA cell in V shaped molecular form. Reproduced from Karim, F., Walus, K., Ivanov, A., 2010. Analysis of field-driven clocking for molecular quantum-dot cellular automata based circuits. *Journal of Computational Electronics* 9, 16–30. Lent, C., Isaksen, B., 2003. Clocked molecular quantum-dot cellular automata *IEEE Transactions on Electron Devices* 50, 1890–1896.

Fig. 8 Molecular cell dimension.

Fig. 9 Plot of cell size (nm) Vs V_{rms} for three different spacing of electrodes. Reproduced from Karim, F., Walus, K., Ivanov, A., 2010. Analysis of field-driven clocking for molecular quantum-dot cellular automata based circuits. *Journal of Computational Electronics* 9, 16–30.

The RMS voltage V_{rms} can be defined as $\sqrt{(V_1^2 + V_2^2)}$. Where V_1 is maximum allowable V_{avg} and V_2 is minimum allowable V_{avg} (Karim *et al.*, 2010). The interdependency between cell size and RMS voltage is studied and analyzed in Fig. 10. A spacing of 20 nm (Karim *et al.*, 2010) is applied while selecting V_{rms} and cell size. While selecting the above two parameters we need to analyze the temperature issues also. Now maximum applicable phase difference ϕ_{max} between two adjacent electrodes having maximum potential difference ΔV_{emax} can be expressed as,

$$(\phi)_{max} = \pm 2\sin^{-1}\left(\frac{\Delta V_{emax}}{2V_0}\right) \text{ radians} \quad (6)$$

Here, V_0 is peak potential value of clock signal applied to adjacent electrodes and the minimum RMS voltage should be applied (Karim *et al.*, 2010). The inter-electrode spacing is maintained at 20 nm. The ground plate is placed $\eta = 25$ nm above the electrodes and cells are placed $\beta = 23$ nm above the electrodes as depicted in Fig. 11. The length and radius of electrode are chosen to be 100 nm and 5 nm respectively as justified in article (Visconti *et al.*, 2004; Liu *et al.*, 2002). Dielectric like SiO_2 is used between electrodes and molecules whose dielectric constant is 4.2. The electrodes shall be buried inside the dielectric (SiO_2) (Nojeh *et al.*, 2004).

Analysis of field-driven clocking for molecular quantum-dot cellular automata based circuits. *Journal of Computational Electronics* 9, 16–30.

Proposed Methodology for the Generation of X-ray

If cell size is allowed to decrease, reduced RMS voltage and maximum operating temperature can be regulated as analyzed in Fig. 12. At 1000–1300K, an array of cells having dimension of 1 nm can be employed with an RMS value of 2–2.81 V_{rms} voltage magnitude approximately (Karim *et al.*, 2010). Application of clock signal energizes the electrons and bring them to the NULL state. Application of input signal decides polarity when applying simultaneously with the clock signal. Tunneling electrons possess dual wave particle property (Zetili, 2009; Blum, 2012). Each electron particle, while moving through the tunnel, behaves as a group of waves as per de-Broglies hypothesis on matter waves (Zetili, 2009; Blum, 2012). According to this hypothesis this group of waves is nothing but superposition of several monochromatic waves with same amplitude and phase but marginally different wavelength (Baym, 1969; Fock, 1986). Let $\psi(x)$ be the superposition state of an electron tunneling between the dots in the x direction. Fourier transform expresses the superposition state $\psi(x)$ of an electron as (Fig. 13),

$$\psi(x) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} (\phi)(k) e^{i(kx)} dk \quad (7)$$

where $\phi(k)$ is the amplitude of the superposition wave. $k = \frac{2\pi}{\lambda}$ is the wave propagation velocity. λ is the wavelength and $i = \sqrt{-1}$. Fig. 14 shows the characteristic curve of an electron wave while moving through channels (Mukhopadhyay and Dutta, 2015). Whenever electron is localized, it is positioning at $x=0$ and at this position $e^{i(kx)} = 1$. It means electron waves of different frequencies interfere constructively and no oscillations are reported. Hence $\psi(x)$ attains peak at $x=0$. At other values of x , the components of $e^{i(kx)}$ are added up as in Eq. 7. Thus resulting in oscillations and the value of $\psi(x)$ is obtained. At $\frac{x}{2}$, $e^{i(kx)}$ attains minimum value and characteristic curve achieves the negative peak. When x grows from this point, the value of $e^{i(kx)}$ also grows resulting in growth of $\psi(x)$.

As stated earlier, clock signal in QCA is the energy supplier for the electrons to change their state. We assume that inter-dot channels are experiencing finite potential energy $V(x)$ in the positive x direction. Then time independent Schrödinger wave equation is,

$$\frac{d^2\psi(x)}{dx^2} + \frac{2m}{\hbar^2} (E_n - V(x))\psi(x) = 0 \quad (8)$$

where m is the mass of electron, $\hbar$ is reduced plank constant, E_n is the infinite sequence of discrete energy levels corresponding to all possible nonnegative integral values of n . Here, n is representing the quantum number. Eq. (8) can be reduced to

Fig. 12 The plot depicts a trade off between maximum operating temperature in K, cell size in nm and RMS voltage in volt. Reproduced from Karim, F., Walus, K., Ivanov, A., 2010. Fig. 14 Characteristic curve Reproduced from Mukhopadhyay, D., Dutta, P., 2015. A study on energy optimized 4 dot 2 electron two dimensional quantum dot cellular automata logical reversible flip-flops. *Microelectronics Journal* 46, 519–530.

$$E_n = \frac{n^2 \pi^2 \hbar^2}{2md^2} + V(x) \quad (9)$$

where d is the molecular cell dimension (Mukhopadhyay and Dutta, 2015). If applied voltage to the molecule is V volt and junction capacitance is C then, an expression can be generated as (Mukhopadhyay and Dutta, 2015),

$$\frac{\pi^2 n^2 \hbar^2}{2md^2} + V(x) = \frac{1}{2} CV^2 \quad (10)$$

This expression will eventually be useful in calculating operating RMS voltage of the system.

We assume that two discrete energy states E_{n_1} and E_{n_2} correspond to two quantum numbers n_1 and n_2 . Electron may transit from one energy state to another if sum or difference of quantum numbers is an odd number (Mukhopadhyay and Dutta, 2015). We need to find out the n th quantum number such that while transiting from this state to ground state, a cell radiates energy between 5×10^3 eV to 10^4 eV. This transition is expressed as,

$$\Delta E_n = E_n - E_1 = \frac{\pi^2 \hbar^2}{ma^2} (n^2 - 1) \quad (11)$$

X-ray generating system requires to radiate X-ray energy in the range between 5×10^3 eV to 10^4 eV. Considering lowest energy value i.e., 5×10^3 eV to be equal to ΔE in Eq. (11), we deduce a relation between electron quantum number (n) and cell dimension (d) as,

$$n^2 - 1 = 13.29 \times 10^{21} d^2 \quad (12)$$

Again considering the highest energy radiation i.e., 10^4 eV and equating it to ΔE_n in Eq. (11), the relation between electron quantum number n and molecular cell dimension d can be expressed as,

$$n^2 - 1 = 2.66 \times 10^{22} d^2 \quad (13)$$

A careful study of Fig. 12 reveals that at temperature of 1000K and at 2 V_{rms} operating voltage the cells attain a dimension of 1 nm considering potential energy of an electron to be 5.82×10^{-20} Joules and junction capacitance to be 200 atto-farad. If molecular cell dimension is considered to be 1 nm, for lowest level of X-ray radiation, Eq. (9) produces the value of n to be 116. If we apply the same methodology in Eq. (11) for highest limit of X-ray radiation, the value of electron quantum number n can be deduced to be 162, the temperature is modified to 1300°C at 2.81 V_{rms} applied voltage. For a single molecular cell the Eq. (11) can be reformed as,

$$(v)_2 = \frac{\pi \hbar}{2md^2} (n^2 - 1) \quad (14)$$

where v_2 is radiation frequency.

Eq. 14 derives $v_2 = 4.8 \times 10^{18}$ Hz with $n=162$ and $d=1$ nm and $v_2 = 2.446 \times 10^{18}$ Hz with $n=116$ and $d=1$ nm which lies between 1×10^{18} Hz to 3×10^{19} Hz, the frequency range of existing X-ray for X-ray system. The above calculations are for single molecular cell. The radiation energy strength for N number of molecular cells arranged in cascade is computed between $5 \times 10^3 \times N$ to $10^4 \times N$.

QCA Molecular X-ray (QX-ray) System

Our finding is a portable X-ray system consisting of X-ray generator and X-ray detector. We are going to propose X-ray generator only. Portable X-ray detectors are already available. The existing X-ray generator is huge in size and permanently housed in a room. The patients are to be brought physically to the X-ray room for imaging. Sometimes this movement becomes very painful for patients having fractures and/or bone disorders. Our invention is directed towards these kind of patients to give them some relief from additional pain of movement. The proposed X-ray generator system along with X-ray detector will be brought to the patient site. The image taken in digital form will be stored temporarily with the detector and later it will be analyzed at the laboratory.

Proposed X-ray Generator System

Existing X-ray systems suffer from many drawbacks. The focal spot at anode may attain a temperature level of approximately 2500°C and anode assembly may reach a temperature of around 1000°C. They use a high voltage power source of approximately 150 kilo volt (kV) (Coolidge, 1917; Langmuir, 1917). Another major drawback observed in the existing generation methodology is that approximately about 1% of the energy is radiated as X-ray and the rest is released as heat (Donnelly, 2005; Jens and Des, 2001). Our proposed system should overcome these drawbacks. Table 1 lists comparative studies on existing and our proposed X-ray system. The list suggests the superiority of the proposed system against the existing counter part.

The invention consists of an X-ray plate containing an array of cells as shown in Fig. 16(a). Each cell in the plate will be replaced by the molecular counter part as shown in Fig. 16(b). The cross section of X-ray generator is depicted in Fig. 15. At the lowest level

Fig. 17 (a) X-ray plate. (b) Molecular cell that will replace the square cells in X-ray plate.

electrodes are arranged. These are buried under oxide layer. The details about electrodes and dielectric are provided in Section “Molecular System Clocking Arrangement”. The molecular cells are arranged over this layer as in Fig. 16(a). Above this layer of cells, ground plane is placed. The cell size of 1 nm may work at temperature between 1000K and 1300K at 2–2.81 RMS voltage. So there is need for temperature control and electrodes might be supplied with the required RMS voltage employing step down

Fig. 18 X-ray tube containing power supply section.

transformer. **Fig. 17** depicts X ray tube containing power supply. Power supply is housed at the back of the tube. It contains electrodes and oxide layer. A ground plate will be located at the top of electrodes. X ray plate containing an array of QCA cells is placed at the top of power supply section. Radiation coming out from plate is directed towards radiation head.

Portable X-ray Detector

Portable X-ray detector (Lanca and Silva, 2009; Uffmann and Schaefer-Prokop, 2009) is already available in the market. The proposed X-ray system as shown in **Fig. 18** consisting of the X-ray generator and X-ray detector may be brought to the patient site. The image created will be detected by the proposed X-ray detector. The detector will convert it into electrical signal and may store information temporarily.

Hollow Waveguide or Capillaries

X-ray wave is difficult to direct. Different techniques are employed to direct X-ray beams such as optics based on total reflection principle such as capillary, natural crystals and multilayer optics i.e., man made layered structures etc. X-ray after generation are scattered everywhere unless we place an hollow parabolic waveguide just after X-ray tube as apparent in **Fig. 18**. The hollow parabolic wave guide may be made from Carbon Nano Tube (CNT) or glass as reported in patents (Verman and Jiang, 2011; Aharon Bar-David and Harel, 2014).

Conclusion

The present disclosure is a proposal of nature friendly X-ray generating system. This technology may consume green energy generated from harness natural processes such as geothermal energy, wind energy, biomass energy, solar energy, Hydro-electric power etc for system execution. This nano-technology based system places itself as appropriate for environmental point of view. Thus the proposed methodology may eliminate any chances of generation of greenhouse gases and keeps the environment clean and worth living.

Use of Clean, Renewable and Alternative Energies in Mitigation of Greenhouse Gases

Ratna Dutta, Jadavpur University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Climate change is now a global concern because it has deep repercussion on both human and natural systems. The impacts of climate change are observed in occurrence of floods, storms, snowstorms, tsunamis, droughts, tornados in greater frequency, stretch of infectious pests, pathogens and heat waves. It also results alarming rate of extinction of species and biodiversity loss. Climate change is basically based on global warming due to augmented concentration of greenhouse gases (GHGs) in the Earth's atmosphere (Elum and Momodu, 2017). The attempt to mitigate the causes of high concentration of greenhouse gases (GHGs) is accepted throughout the world as one of the best approaches to arresting climate change. To keep global warming well below 2°C or even below 1.5°C requires a fundamental restructuring of important areas in the economy and society. Solution to the problem lies in the implication of clean air policies by using renewable energies, increasing energy efficiency, reducing extremely climate-damaging fluorinated greenhouse gases (F-gases) and as well as sustainable mobility and city planning (Owusu and Asumadu-Sarkodie, 2016; Kang and Holbrook, 2015; Raghuvanshi *et al.*, 2008). On the other hand, sustainable development for prevention of climate change is also global concern which can be duly handled by use of renewable energy resources.

Renewable energy refers to harnessing energy from natural sources like solar, wind, hydro, geothermal energy and even rivers, biomass which produces very small amounts of greenhouse gases during combustion. Therefore, it refers as sustainable route of energy production and as well as clean energy source. The dominance of fossil-fuel based power generation (coal, oil & gas) and exponential increase in energy demand due to huge population growth results global challenges associated with rapid increase in concentration of carbon dioxide, which is an important greenhouse gas. In a developing country like India, the growth rate of electricity generation is 5.5%; it increased to 212 GW from 106 GW within 1996–2010 (Raghuvanshi *et al.*, 2008). It is predicted that globally energy related emission would increase by about 16% by 2040 (Elum and Momodu, 2017). Second big contributor to GHGs emission in the environment is the combustion of conventional transport fuel which is derived from fossil fuels. In 2010, transportation sector contributed 27% of total GHGs emission in United States (Kang and Holbrook, 2015). Actually, United States, Australia and Canada are identified as world's highest per capita carbon emitter (Elum and Momodu, 2017). Major portion of CO₂ and other GHGs are emitted from cars and trucks. It is reported that around 62% transport sector emission comes from light-duty vehicles (LDVs) including cars and trucks (Kang and Holbrook, 2015). Use of renewable energy may be a valuable solution to all these problems. Renewable energy can be utilized to produce electricity, vehicles fuels and as well as heat.

This study actually identifies the sources of renewable energy and their potential applications in support of GHGs mitigation attempts for climate change alleviation and sustainable development. Next section of the research focuses on greenhouse effect and greenhouse gases and their abatement policies with global and national perspective. Third section describes the various types of renewable energy options and their mode of uses.

Background

Greenhouse Effect

The 'greenhouse effect' is an atmospheric, natural heating phenomenon in which the Earth atmosphere and surface experiences heating because of presence of certain gases in the atmosphere. Part of incoming solar radiation is reflected back to the space and rest is absorbed by earth surface. Earth emits absorbed energy as infrared radiation (heat) which is partly trapped and re-emitted in all directions by greenhouse gases (GHGs). Some portion of emitted radiation from GHGs absorbed by earth surface again which makes earth warmer. This natural process is called 'Greenhouse effect'. If these gases wouldn't trap heat and emit radiation in the atmosphere, the temperature of the earth would be about 33°C colder on average. Therefore, 'Greenhouse effect' is the key factor to sustain life on earth. In global scale, the key greenhouse gases are carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O) and Fluorinated gases (F-gases). Among them, CO₂ is the most responsible gas for the phenomena because of its larger quantity in atmosphere. Although the greenhouse effect is a natural phenomenon and is one of the reasons that life can exist on Earth, the greenhouse effect is getting worse day by day. At the present, temperature of the earth is steadily rising over the years and causes global warming. The problem of climate change and global warming occurs when enormous amount of GHGs accumulate in the atmosphere, increasing the amount of radiation that is absorbed by the atmosphere and re-emitted back to the Earth's surface. The "enhanced" greenhouse effect is caused by anthropogenically produced GHGs. Combustion of fossil fuel is the primary source of CO₂. It can also be produced from direct human-induced impacts on forestry and other land use, such as through deforestation, land clearing for agriculture. Agricultural activities, waste management, energy use, and biomass burning all add to CH₄ emissions in the atmosphere. The main sources of N₂O emissions are agricultural activities, such as use of fertilizers. Fossil fuel combustion also generates N₂O. F-gases are mainly formed from various industrial processes, refrigeration, and due to the use of a variety of consumer products.

To avoid an irreversible build-up of GHGs and eventually global warming and climate change, we should act immediately because only few years are left as our “breathing space” (Mac Kinnon *et al.*, 2018; Fernandez *et al.*, 2005). Like other countries with developing economies, India faces the dual challenge of merging its rapid economic growth with a persistent need to address climate change. India is a large developing country with huge rural population directly depending on natural resources like water, mangroves, coastal zones, grasslands and their survival & existence depends on forestry, agriculture and fisheries. The potential impacts of climate change are often various and different regions have differential vulnerabilities to climate change. ‘The Climate Modeling Forum’ of India (consists of several independent research institutions, e.g., NCAER, TERI, IRADe, and Jadavpur University) supported by the Ministry of Environment & Forests, Government of India published a report (see “Relevant Websites section”) in September 2009 indicating the GHG emissions trajectory of India for the next two decades, using a number of different techniques. One report (see “Relevant Websites section”) shows that India’s per-capita CO₂ emissions in 2030/31 would be between 2.77 and 3.9 tons per-capita, or little higher like 5 tons per-capita. Another report was published under the umbrella of “MAIN – Mitigation and Adaptation Information Network” for Sustainable communities by Development Alternatives (DA) in association with UNEP/GRID-Arendal named as “Climate Change Mitigation in India” which focuses on the efforts taken up by the Government of India towards climate change mitigation and how the environmental concerns have been integrated in Indian planning process (see “Relevant Websites section”). The basic findings of the report indicates that main contributor sector of GHGs emission are energy, industry, agriculture and waste (Fig. 1) (see “Relevant Websites section”) and per capita CO₂ emissions was 1.5 tonnes in 2007. The energy sector is broadly divided into sub-section: electricity generation and transport where the first sector is the giant supplier.

In global perspective, in 2014, the top carbon dioxide (CO₂) emitters were China, the United States, the European Union, India, the Russian Federation, and Japan (Fig. 2). These data include CO₂ emissions from fossil fuel combustion, as well as cement manufacturing and gas flaring and presented in Fig. 2.

GHG Mitigation and Abatement Options

Mitigation and abatement activities aims to either reduce releases of GHGs or increase removals of GHGs from the atmosphere. Initiatives involving to substitute GHG-producing activities with non-GHG producing activities are reduction approaches (Pahuja *et al.*, 2014; see “Relevant Websites section”; Reck and Hoag, 1997).

Fig. 1 Sectoral GHG emission in 2007 [http://www.devalit.org/knowledgebase/pdf/CDM_Report.pdf,\(2011\).](http://www.devalit.org/knowledgebase/pdf/CDM_Report.pdf,(2011).)

Fig. 2 Global CO₂ emissions from fossil fuel combustion and some industrial processes. Reproduced from Boden, T.A., Marland, G., Andres, R. J., 2017. National CO₂ Emissions From Fossil-fuel Burning, Cement Manufacture, and Gas Flaring, Carbon Dioxide Information Analysis Center, Oak Ridge National Laboratory, U.S. Department of Energy, pp. 1751–2014.

Reduction option can be implemented by:

- Industrial process modifications,
- Renewable energy transitions,
- Demand side efficiency improvement,
- Prevention of deforestation.

On the other hand, approaches of capturing GHGs that have already been produced by various sequestration technique (i.e., storage of captured gas) is the second possible route of mitigation and abatement of GHGs.

Sequestration of various types:

- Forest sequestration,
- Agricultural sequestration,
- Geological sequestration,
- Ocean sequestration,
- Mineral sequestration.

Capturing and use is the last but best possible route of mitigation of GHGs. This includes:

- Methane capture,
- Biomass to energy,
- Biomass to product.

Under this category, GHGs are captured from atmosphere and then converted into products and used as energy sources that substitute for GHG-producing activities. For example, a crop such as corn might be grown to produce ethanol, which then replaces the use of fossil fuels.

Clean and Renewable Energy Options

Renewable energy can be defined initially as any energy source that is converted directly or indirectly from solar energy. In the broadest sense, however, almost all of the energy, including fossil fuels, can be considered a form of solar energy. The most widely used forms of non-renewable energy, such as wood, oil, gas, and coal, are embodied forms of solar energy collected, stored, and converted by natural processes. Till date approaches to energy are non-sustainable and non-renewable and the world's energy supply is largely based on fossil fuels and nuclear power. These sources of energy will not last endlessly and have proven to be contributors to our environmental problems like emission of GHGs. Due to continuous increment of global need of energy associated with economic growth and industrial revolution; mankind has already exhausted roughly half of the fossil fuels that accumulated under the earth's surface over hundreds of millions of years. Availability of nuclear power is also depends on a limited resource (uranium) and the use of nuclear power creates such countless risks that nuclear power plants cannot be considered as reliable source of energy. Therefore, the main problem of 'scarcity' will remain, and this represents the greatest challenge to mankind in next decades onwards. Renewable energy can now be defined as forms of solar energy that are available and replenished in time scales no longer than human lifetimes.

Renewable energy basically comes from the sun directly or indirectly. These sources of energy supply opportunities for countless, sustainable and replenishable energy supply with almost no environmental effect. Renewable energy offers to reduce carbon emissions, clean the air, and put our civilization a sustainable solution of energy demand. On the other hand, it helps to reduce dependence of energy imports, thereby ensuring an obvious economic growth via sustainable supply and climate protection. Renewable energies will offer a more diversified, balanced, and steady pool of energy sources.

There are several renewable energy sources that are in use today (Sathaye and Meyers, 1995; Alrikabi, 2014):

- Solar energy,
- Wind power,
- Hydropower and tidal energy,
- Geothermal energy,
- Biomass energy,
- Fuel cell.

The major technologies available to harness various forms of renewable energy from their sources and its applications are listed in **Table 1** (Sathaye and Meyers, 1995; Alrikabi, 2014). Although many of these technologies are still under development, most have come in commercial markets around the world. Research and development activities continue to improve all of these systems to enhance their ability to meet future energy demands.

Renewable Energy Sources and Technologies

Renewable energy is called as alternative energy, an alternative to fossil fuels from 1980s. In 2009, about 18% of global final energy consumption came from renewables, with 13% coming from traditional biomass and 3% from hydroelectricity (**Fig. 3**)

Table 1 Renewable energy sources and relevant energy technologies available with their end-use applications

Resource	Technology	End-use applications			
		Electricity	Industry	Building	Transport
Solar energy	Photovoltaics – Flat plate	✓			
	Photovoltaics – concentrator	✓

Fig. 3 Global Final Energy Consumption, 2006 (REN21, 2007, Global Status report). Reproduced from El Bassam, N., 2011. Renewable Energy Sources and Their Applications (Chapter 1). Agrobios International.

(El Bassam, 2011). New renewables (small hydro, modern biomass, wind, solar, geothermal, and biofuels) accounted for another 2.8% and is growing very rapidly. The share of renewables in electricity generation was around 19.4%, with 16.1% of global electricity coming from hydroelectricity and 3.3% from new renewable (El Bassam, 2011). In the country like India, the potential capacity of renewable energy source is estimated to be 126,000 MW including ocean, tidal, thermal power (Raghuvanshi *et al.*, 2008). Maximum potential is available as wind power (45,000 MW (Raghuvanshi *et al.*, 2008)) but achievement is highest in exploiting hydro power capacity (Raghuvanshi *et al.*, 2008).

Solar Energy

Solar energy is abundant, it has the greatest potential for providing clean, safe, and reliable power. Both usable electricity and heat can be produced from sun's light. Statistics indicates that the annual total solar energy is 1×10^{18} kWh, which is just equivalent to

13 trillion tons of standard coal and about 1000 times more than the oil reserves. Total available solar energy is ten thousand times more than the world's energy necessity. Solar Energy can be classified into two types: active solar and passive solar or photovoltaic and thermal. Electricity can be produced directly from photovoltaic, while solar thermal systems produce heat for buildings, industrial processes or domestic hot water. Thermal systems can also be utilized to generate electricity by operating heat engines or by producing steam to spin electric turbines. Solar energy systems have no fuel costs, so there is only original investment in the equipment. The main types of solar energy technologies are (Sathaye and Meyers, 1995):

- Photovoltaic (PV) systems convert sunlight directly to electricity by means of PV cells made of semiconductor materials.
- Concentrating solar power (CSP) systems concentrate the sun's energy using reflective devices such as troughs or mirror panels to produce heat that is then used to generate electricity.
- Solar water heating systems contain a solar collector that faces the sun and either heats water directly or heats a "working fluid" that, in turn, is used to heat water.
- Transpired solar collectors, or "solar walls" use solar energy to preheat ventilation air for a building.

Photovoltaic systems

A photovoltaic system uses photovoltaic cells (PV) to directly convert sunlight into electricity using modules composed of multiple PV cells. The photoelectric effect was first noted by a French physicist, Edmund Becquerel, in 1839, who found that certain materials on exposure to light would produce small amounts of electric current. In 1905, Albert Einstein described the photoelectric effect. PV generates power on a much smaller scale than traditional utility power plants, so they can often provide high-value electricity exactly where and when it is needed. PVs are often the best choice for supplying power for remote, "off-grid" sites (refer Fig. 4).

The method of conversion of light energy to electrical energy is based on photovoltaic effect. On exposure to light, semiconductor materials can absorb some of the photons and which results some free electrons in the crystal. This is the basis of electricity generation by photovoltaic effect. Silicon is the widely used semiconductor material for constructing photovoltaic cell. A typical PV cell consists of thin two layers: ultra-thin layer of phosphorus-doped (N-type) silicon on top and thicker layer of boron-doped (P-type) silicon (Schumm, 2010). In the top junction, electrical field is generated. When sun light strikes the PV cell, electrical field is produced and results flow of electricity when solar cell is connected to an electrical load. A typical silicon PV cell produces about 0.5–0.6 volt DC under open-circuit, no-load conditions; it does not depend on size of cell. The current (and power) output of a PV cell depends on its efficiency and size (available surface area), and is proportional to the intensity of sun light.

PV devices are used as modules composed of multiple PV cells. Two distinct categories of PV devices are available: flat-plate and concentrating. Flat plate type has huge surface area and utilizes the whole of the incident solar radiation including diffused part. A concentrator system uses lenses to focus radiation on few efficient PV cells and only use direct beam sun-light. Concentrating solar power (CSP) technologies requires mirrors for reflecting and concentrating sunlight onto a point where it is stored as heat and then converted to electricity.

Solar thermal – Electric

Solar thermal technologies collect the sun's radiant energy to create a high-temperature heat source that can be converted into electricity via a number of thermodynamic conversion cycles (Fig. 5).

Parabolic trough technologies employ a field of parabolically-shaped solar collectors. The collectors accept sun's energy and focus onto specially-coated metal pipes surrounded by heat transfer fluid filled glass tubes. The fluid passes through the sunlight collector and becomes very hot. Typical heat carrier fluids are water or steam, oil, or molten salt. Then the fluid is transferred to the heat engine, which converts the heat to electricity. Parabolic dish systems use a modular mirror system that approximates a

Fig. 6 Schematic of a flat plate solar collector. (Pic: <https://www.e-education.psu.edu/eme81>).

parabola and creates a high energy flux at the focal point where an external combustion converts the heat into electricity. Central receivers use a large field of sun-tracking mirrors (heliostats) that reflect the incident radiation onto a tower-mounted thermal receiver. Finally, solar pond systems collect and store solar energy in a liquid medium (usually a large basin of water with a salt gradient), which can then be converted to electricity using a closed Rankine Cycle engine (Sathaye and Meyers, 1995). Two types of collectors are described schematically in Figs. 6 and 7.

Some typical collectors are used which to a bigger energy conversion system. The following designs are used as utility scale solar thermal systems:

- (1) Linear reflectors (heating temperatures $\sim 280^{\circ}\text{C}$),
- (2) Parabolic trough (heating temperatures $\sim 400^{\circ}\text{C}$),
- (3) Dish/engine systems (heating temperatures $\sim 650^{\circ}\text{C}$),
- (4) Solar tower (heating temperatures $\sim > 1000^{\circ}\text{C}$).

Solar building technologies

Building energy consumption is growing day by day. Solar energy, as a type of renewable energy, will greatly alleviate the pressure of the building energy consumption. Heating, cooling or day lightening of buildings can be done using active and passive solar building technologies. Appreciable number of solar water heaters is available in Japan; some other countries like United States, China, Turkey, Kenya and Guinea are also using this technology (Sathaye and Meyers, 1995). Both active and passive solar building designs (Fig. 8) are used though passive is more popular. In case of active design, solar energy collectors receive energy and transfer to a working fluid (water, oil or air) for direct use or storage. This system can provide hot water or heating/cooling of interior space. Cooling technologies include solar desiccant systems that use a drying agent to adsorb water vapour in circulating air to make cooling effect in interior space and solar heat is then used to dry or regenerate the desiccant for re-use (Sathaye and Meyers, 1995). Passive solar design is practiced throughout the world to make buildings with low energy cost and low maintenance cost. No mechanical means are used in this technology; rather, it exploits the thermal energy flow associated with radiation, convection and conduction. Actually, building material can absorb, reflect or transmit solar radiation and air flow is also governed by solar heat; thus living space of the building itself can get heating or cooling effect by itself. Whole success of the technology based upon the choice of building material, placements that can provide heating and cooling effect at home and some

Fig. 7 Types of concentrating sunlight collectors: (a) Tubular absorbers with diffuse back reflector, (b) tubular absorbers with specular cusp reflectors, (c) plane receiver with plain reflectors, (d) parabolic concentrator, (e) array reflectors (heliostats) with central receiver. (Pic: <https://www.e-education.psu.edu/eme81>).

Fig. 8 Solar building technologies (a) Active solar heating; (b) Passive solar heating. (Pic: Wikipedia).

design elements. For passive solar heating, two primary requirements are south facing glass and thermal mass to absorb, store and distribute heat. Passive cooling is done using natural ventilation. Thermal chimneys can create or reinforce the effect hot air rising to induce air movement for cooling purposes.

Therefore, efficiency of active solar design depends on external storage system which captures and store solar energy like heat pumps, radiators. Active solar systems include the following features (Sathaye and Meyers, 1995):

- Flat-plate PV collector panels or modules (many connected panels), usually mounted and stationary are used to collect sunlight.
- The hydronic collectors use liquid and air collectors use air as conductors to store and convert energy.
- Liquid conductors are more common than those that are air-based, as liquid is generally more efficient at conducting heat, though air-based solar systems have the benefit of not freezing characteristics.

In contrast to active solar systems, external devices are not used for passive systems to operate. Generally, south facing glass windows are used to allow sunlight to enter the home and thermal mass like greenhouses, solariums and sunrooms, solar energy captures sunbeams and retain heat. Passive solar systems include following features (Sathaye and Meyers, 1995):

- It usually relies on south-facing windows to convert rays into sunlight.
- Design of passive solar collectors is based on the law of thermodynamics, which suggests that heat transfers from warm to cool surfaces, such as through convection.
- The success of the passive solar system depends on its orientation and the thermal mass of its walls.

Wind Energy

Wind energy actually an indirect form of sun's energy which is always reloaded by sun and formed by differential heating of earth's surface by sun. Around 10 million MW of energy are continuously available from wind energy. Wind energy provides a flexible and environmental friendly option and national energy security at a time when decreasing global reserves of fossil fuels threatens the long-term sustainability of global energy supply. Rotating shaft of wind turbines convert the kinetic energy of the wind to directly mechanical energy (e.g., milling or water pumping) or converted to electric power in a generator. At good windy sites, it is already competitive with that of traditional fossil fuel generation technologies. Like solar energy resource, one of the main challenges with wind power is its intermittence and high inconsistency in availability. But it can be resolved by systematic adjustment in operation cycle and correct strategies to store wind power into grid.

A wind farm actually a set of wind turbines that are linked together to supply electricity to local large population. Wind turbines should be located where there are steady strong winds – though not so strong they would damage the turbines. Ideal sites for wind turbines therefore are (Thresher *et al.*, 2008):

- Away from obstructions such as forests, towers and rocky outcrops. (These would cause the air to swirl around).
- At the highest point possible.

Newer wind turbines are mainly three bladed rotors with diameters of 70–80 m mounted on top 60–80 m towers (Thresher *et al.*, 2008) shown in Fig. 9. The typical turbine installed in United States in 2007 can produce 1.5 MW of electrical power (Thresher *et al.*, 2008). Wind turbines will not work in winds below 13 Km per hour. They work best where the wind speed averages 22 km per hour (Alrikabi, 2014). Though some greenhouse gases and other pollutants are produced during manufacture, transportation and installation of wind turbines but operating wind farm do not emit greenhouse gases or other pollutants. It is less costly than other energy sources and can be installed remote areas too.

Hydroelectric Power and Tidal Power

Hydroelectricity refers to the electricity produced by conversion of energy from flowing water. River or ocean water is used to produce hydropower. It is basically a renewable energy source as (see “Relevant Websites section”) water cycle constantly renewed by the sun. Generation of hydropower is achieved by damming a river or running a pipe (‘Penstock’) from a high water to lower water body (lake, river, sea). The schematic process diagram of hydroelectric power plant is presented in Fig. 10. Water released from the reservoir spins the turbine and using a connected generator, electricity is produced. Pumped storage plants are also operating to supply power during peak hours. Recycled water generally stored into an upper reservoir which in turn used during peak hours. Hydropower technology is now sufficiently developed and widely used. Currently, worldwide around 15% of total electricity demand is fulfilled by hydroelectric power (Sathaye and Meyers, 1995). Though there is limitations of use of hydropower like concern about impact on regional ecosystem near damming area on river, flooding susceptibility in the nearby landscapes; carbon dioxide emission during construction of dam and methane gas emission from lost vegetation of flooded area, but operation of hydropower plants are totally free of GHGs emissions. As per World Energy Council report (2016) (see “Relevant Websites section”) global hydropower installed capacity is 1.21 TW and they reported the list of top hydropower producing countries (refer Fig. 11).

Fig. 9 Close-up view of modern wind turbine in a wind farm. Source: Thresher, R., Robinson, M., Veers, P., 2008. Wind energy technology: Current status and R&D future. In: Proceedings of the Physics of Sustainable Energy Conference, pp. 1–21.

Fig. 10 Schematic of hydroelectric power plant (Pic: Wikipedia).

Fig. 11 Top hydropower producing countries. (Source: World Energy Council, <https://www.worldenergy.org/data/resources/resource/hydropower>).

Like hydropower, Tidal power also uses moving water to spin turbine and produce electricity; but the difference lies on the fact that here hydrostatic liquid head is created due to tides which is controlled by natural gravitational pull of sun and moon. As tides are generated by continuous movement of our planet, it can be considered as renewable source of energy. It is the oldest form of energy generation. Just like dam, tidal barrage is formed to utilize the potential energy generated by the change in height of water between high and low tides, which energy turns the turbine to produce electricity. Like wind turbines, turbine stream generator (TSG) are also used to make use of kinetic energy of moving tides. Coastal area and seashore is abundant in the world which is the source of clean, free, renewable and sustainable energy. But, tidal power plants are expensive to install and it cannot act as consistent supply of energy as it is dependent of tapping of tidal energy. France came up with first tidal power plant and followed by only few countries like China, Russia, South Korea, Canada set up plants. It is reported in the assessment of The Ministry of New and Renewable energy of India that Khambhat in Gujrat, Kutch in Gujrat and Gangetic delta of Sundarbans, West Bengal are the high potential (total around 8300 MW) places for setting up tidal power plant but, the existing plant in Gujrat is of very low in capacity.

Geothermal Energy

In traditional power plants, steam is used to rotate turbine to produce electricity and required steam is produced by burning of fossil fuels. But in geothermal energy plant, used steam is produced from hot water available in the reservoirs few miles or more in the earth surface. Actually, geothermal power plant uses heat of deep inside of the earth. Hot water is pumped from deep underground of earth at high pressure or high temperature steam is directly pumped. At the ground, due to huge pressure drop, hot water converts to

Fig. 12 Schematic diagram of geothermal power plant (Pic: Google image).

steam (or directly produced steam) which in turn spins turbine and produce electricity using connected generator. Then the steams cools off and condenses into a cooling tower and sent back to the ground to complete the cycle (refer Fig. 12).

Geothermal energy, based on high temperature difference between earth core and earth surface, is so called renewable source of energy because the core of the earth will cool after hundreds of millions of years. Unlike other renewable sources of energy, it does not depend on specific weather condition because heat is constantly radiating outward from earth's core to warm up rock, water, gas and other geological material. But, only some portions of earth's interior are accessible by drilling and geothermal gradient is higher than average, act as 'hydrothermal reservoir' (Owusu and Asumadu-Sarkodie, 2016). Basically, three types of geo-thermal power plants are available: dry steam, flash steam and binary cycle (Sathaye and Meyers, 1995). Dry steam power plant produce steam from the reservoir to form electricity, no liquid water will be with steam; requires no steam separator. But, in flash steam plant, hot liquid water is pumped at high pressure and flashed at surface at low pressure; vapour-liquid separator is used to use only steam in the turbine. In binary cycle, slightly cooler water (at around 57°C) is used to heat separate binary fluid that has lower boiling point (Sathaye and Meyers, 1995). Geothermal energy generation units are already installed in California (US), Philippines, Mexico, Japan, Italy, New Zealand and other countries (Sathaye and Meyers, 1995). The world's largest geothermal power station was set up in California, The Geysers with capacity around 750 MW (El Bassam, 2011). Geothermal electric capacity is touched more than 3000 MW in United States. As per report of EAI, India's leading consulting and research firm, Iceland has a big capacity geothermal unit which contribute 25% of total electricity demand and they reported that India has good potential (10,600 MW), but only 100 MW capacity has been utilized yet. Due to limited size and location of reservoirs, recently engineered geothermal system (formally, hot, dry rock geothermal) which are called as 'Enhanced Geothermal Systems (EGS)' (Reck and Hoag, 1997) are in use.

Biomass and Bioenergy

Bio-energy which is in principle derived from biomass includes any kind of energy obtained from plant materials that range from agricultural and forestry waste, food industry waste, sewage, municipal solid waste to dedicated woody energy crops (Sathaye and Meyers, 1995) and as well as from animal waste. Since biomass (refer Fig. 13) is available in abundance in any country, it can be considered as potential alternatives for energy problem. There are various technologies to harness bioenergy from their feedstock based on digestion, combustion or decomposition. Bioenergy is a significant source of energy which can be used for transport fuel using biodiesel, electricity generation, cooking and heating. It is reported that biomass promises for 79.4% of the total renewable energy supply (Boyle, 2004; Foster, 2007) and comprehensive study of World Energy council (Faaij, 2008) indicates that almost 30% of total world energy demand in 2100 will come from bioenergy. With biomass, lot of research work is aiming to produce sustainable and environmentally acceptable source of energy. Bioenergy has the potential to cut CO₂ emission and decrease global warming. Though, sustainability of the bio-fuel sources (refer Fig. 13) is ensured but debate has been raised between *first generation* and *second generation* bio-fuel. Basically, *1st generation* bio-fuels are those which comes from the feedstock directly; like mainly food crops as oil seeds (rapeseed, palm oil), starch crops (cereals, maize) or sugar crops (sugar beet, sugarcane) (see "Relevant Websites section", Naik et al., 2010; Alam et al., 2015). It is mainly characterized by its capability to produce biodiesel, bio-ethanol and biogas which can be blended with petroleum based fuels and combusted in conventional combustion engines (Dellomonaco et al., 2010). But, recently, use of *1st generation* bio-fuel is under some challenges. Food-versus-fuel debate is the first concern about *1st generation* bio-fuel due to rising food prices and competition of land use with food crops when the feedstock is non-food type crops. Not only that, relatively low GHGs abatement, relatively high marginal carbon abatement cost make threat to commercial use of *1st generation* bio-fuel (see "Relevant Websites section"). Therefore, *2nd generation* bio-fuel produced from lignocellulosic feedstock, become more attractive in commercial use. But, in lignocelluloses, sugars are present as complexly bind as chain and type of sugar is also different from that present in sugar crops. Therefore, conventional fermentation using microorganisms is not

Fig. 13 Source of biomass used as feedstock for bio-refineries. Reproduced from Sikarwar, V.S., Zhao, M., Fennell, S., Shah, N., Anthony, E., 2017. Progress in biofuel production from gasification. *Progress in Energy and Combustion Science* 61, 189–248.

sufficient to produce bio-ethanol and appropriate method of bio-ethanol production should be supported by suitable pretreatment process which helps to remove the unconvertible lignin part. Fermentation process is preceded by advanced pretreatment and enzymatic hydrolysis processes to remove out sugar. Though it is non-competitive with food but advanced technologies are still under development to reduce the cost of conversion. Latest reports suggest that microalgae are recently promoted as 3rd generation bio-fuel (Larson, 2008; Sikarwar *et al.*, 2017). Starting from methane, biodiesel, bio-hydrogen type of renewable bio-fuels can be obtained from microalgae (Larson, 2008). It is reported that it can give 15–300 times more biodiesel than traditional crop on area basis (Larson, 2008). Moreover, it does not require high quality agricultural land to grow and its growth rate is too fast. Therefore, it may be a viable alternative. The various routes for production of bio-fuels are described in Fig. 14.

Conversion processes for 1st generation bio-fuels

Transesterification

Oil seed crops are mainly used to produce bio-oil containing triglyceride which converts to fatty acid methyl esters (FAME) in presence of alcohol and catalyst (homogeneous/heterogeneous) by saponification reaction. This conversion step is based on transesterification. The FAMES of bio-oils are popularly known as biodiesel. Biodiesel can easily replace diesel fuels due to having comparable or rather superior fuel quality (Alam *et al.*, 2015; Sikarwar *et al.*, 2017; Dellomonaco *et al.*, 2010). The Transesterification (alcoholysis) reaction is shown in Fig. 15 where catalyst may be a liquid acid/liquid base or solid catalyst. Basically, homogeneous catalysis using liquid catalyst is preferable with high triglyceride containing oil but heterogeneous catalysis using solid catalyst is performed when oil contains less triglycerides and high free fatty acids. In the both the cases final products are same. Catalysts are regenerated and use of excess alcohol favours the ester formation.

Ethanol conversion process

Ethanol production is obtained by enzymatic hydrolysis of starch containing crops and specifically fermentation process of sugar containing crops and cellulosic biomass too. The alcohol produced from food crops is known as grain alcohol and ethanol produced from lignocellulosic biomass is termed as bio-ethanol (Alam *et al.*, 2015). Grains like wheat, barely, rice, corn etc., are starch containing crops and sugar cane, beet root, fruits etc. are sugar containing crops. In fermentation process, organic substrate undergoes chemical changes in presence of enzymes secreted by micro-organisms which are available in nature.

Though stoichiometrically, ethanol conversion efficiency is 51% on weight basis, but roughly 40%–48% efficiency is available (considering consumption of glucose by microorganism itself), i.e., 583 lit of pure ethanol can be obtained from 1000 kg fermentable sugar (Alam *et al.*, 2015).

Conversion processes for 2nd generation bio-fuels

Thermo-chemical conversion

Pyrolysis, gasification and liquefaction are three important routes of thermo-chemical conversion technologies to synthesize bio-fuels from biomass. All the processes are high temperature and sometimes high pressure process. Biomass is generally heated

Fig. 15 Transesterification reaction. Source: Wikipedia.

under oxygen deficient condition to reduce oxygen content of biomass and enhance fuel quality. Syngas is a obvious by-product of the processes which can be used as fuel directly or can be processed to produce other products.

Pyrolysis is basically thermal degradation of biomass at high temperature (300–500°C) in absence of oxygen. It results charcoal (solid), bio-oil (liquid) and fuel gaseous products). Significant amount of bio-oil can be produced without pre-treatment of raw material; but produced bio-oil requires extensive treatment prior to use as bio-fuel oil.

Thermo-chemical conversion of lignocellulosic biomass by reacting with synthesis gas at comparatively lower temperature range 250–450°C and high pressure (5–20 bar) gives liquefaction of biomass and results water insoluble bio-oils (Alam *et al.*, 2015; Dellomonaco *et al.*, 2010). Bio-oil produced by liquefaction has lower oxygen content than oil produced by pyrolysis; so it requires less extensive treatment.

Gasification is the oldest technology among them. It is the thermochemical conversion of solid or liquid biomass into a mixture of carbon monoxide, carbon dioxide, methane, hydrogen, nitrogen, tar, water vapour, hydrogen sulfide at very high temperature (1300°C). it involves reaction between biomass with air, oxygen or steam. Producer gas and syn gas are directly used as fuel. Using Fischer-Tropsch synthesis, syn gas can be converted to hydrocarbon fuels.

Conversion processes for 3rd generation bio-fuels

Microalgal biomass can be converted to energy sources by various ways like biochemical conversion, thermo-chemical conversion; chemical reaction and even direct combustion (refer Fig. 16). Oil content of algal biomass is around 30% (Alam *et al.*, 2015) and around 70% algal by-products are formed which are used as raw materials in some other industries. Both biodiesel and bio-ethanol are from algal lipids (and free fatty acids) and algal starch (and proteins) respectively. Lots of challenges remain in commercialization of this bio-fuel conversion route.

Fuel Cell

Fuel cell combines hydrogen and oxygen to form electricity, heat and water. Like batteries, fuel cell produces electricity in cost of chemical reaction. Fuel cell can power tiny microchips to buildings to buses. Fuel can use a variety of fuel like hydrogen, ethanol, methanol, various acids and even various bases but it run best by hydrogen. Unlike batteries, it does not get exhausted, gives continues supply of electricity. In future, it may be a viable alternative fuel.

Fig. 16 Bio-fuel production processes from microalgal biomass. Reproduced from Dellomonaco, C., Fava, F., Gonzaliz, R., 2010. The path to next generation biofuels: Successes and challenges in the era of synthetic biology. *Microbial Cell Factories* 9, 3.

Use of residential fuel cell is being popular now-a-days. It is very efficient since it can convert chemical energy to electrical energy directly; without combustion and with clean emission. If hydrogen is used in fuel cell, in presence of reformer, converts fuels to hydrogen and emits water vapour and carbon dioxide. Fuel cells are compatible with other renewable sources of energy. It can be run by chosen fossil fuel and as well renewably generated hydrogen. This particular source of energy is very much flexible and can be easily maintained. But the main limitation of using is high cost of the source.

Conclusion

Within this review, it has been demonstrated that renewable energy resources have adequate potential to support sustainable energy strategies over time that can achieve the GHG reduction and air quality improvement sought by society. Energy is a requirement of everyday life and demand for energy is growing exponentially with progression of technologies, up gradation of lifestyle and augmented attention towards economic growth and productivity. Renewable energy not only improves health and environmental quality rather it gives economic benefits too. Harnessing of renewable energies is basically labor-intensive than fossil fuels; creates job opportunities in utility companies. Basically, renewable energy is the stable and abundant resource for energy need. Though renewable energy sources are acknowledged as alternative fuels to fossil fuels, but use of them is still limited and infrastructure development to use them is still need to cross some barriers like cost, political environment, market condition and awareness. Renewable energy has significant contribution to heat and transport fuel but the progress is slower. Few basic disadvantages of use of renewable energies are identified already. Many forms of renewable energies are not commercially viable like tidal power, geothermal power and some forms of renewable energies are location specific or weather specific like solar power, wind power which needs storage capabilities for constant supply of them. Complete pollution free status can not be attained by use of renewable energies because the technologies and services that are used to build renewable energy resources require burning of fossil fuels. Some forms of renewable energies require enormous space also. Renewable energy policies for transport sector are focused in bio-fuel blending mandates, subsidies or combination of both. Now, a systematic approach for tracking the progress and impact of mitigation actions for GHG inventory system at corporate, city, state, nation and international levels is an important way to ensure effective implementation of the planning for clean and green 'Earth'.

Introduction

Man's Hunt for Energy

Civilization has always been driven by the energy where as resource handling for energy has transformed over the time. Previously, people and their domestic animals relied on food as a resource for energy. Worldwide, the social order is determined on a novel and sustainable food sources. New processing methods for the preservation of food could also be utilized with increased effectiveness and producing less waste. Individuals relocated across the continents in the light of complex societal demands, but certainly, search for a constant supply of energy was a general feature in those migrations (<http://www.extremetech.com/extreme/124383-bacteria-converts-carbon-dioxide-into-liquid-fuel>). Likewise, there is rather an endless search of mankind for the recovery of energy from the substances that once would have been viewed as nourishment, yet now are exclusively planned to create energy like biofuels (David and Wiegman, 2010). These consequent advancements caused cutting of the trees and contended with once likely just for agricultural practices. By 13th Century, Europeans had acquired the knowledge regarding the Chinese gunpowder; this made a further interest for charcoal once more (Medina-Ramos *et al.*, 2014). The exploitation of gunpowder dictated by the military for chucking of guns has needed a lot more of charcoal (Medina-Ramos *et al.*, 2014). These elements influenced the necessities of time required for charcoal creation, prompting presentation of boundaries in specific nations. By the 18th century, the interest in charcoal that promoting iron business was huge to the point and option was appealing, which was started coke as an alternative fuel (Medina-Ramos *et al.*, 2014). The recorded connection between coke and coal showed how single energy source could lead to numerous collaborating uses along with its constraints and the resultant trade that associates the difficulties in the usage. Aside from searching for new arrangements and growing new techniques for resource creation, energy engineers have a reasonable response to help the approach creators and the overall residents of the upsides and downsides of every means of energy generation (Hu *et al.*, 2018).

Fossil Fuels

In the course of the past, fossil fuels are framed by usual routes, for example, the anaerobic disintegration of buried dead-living beings, for the period of the revelation of high temperature and pressure of earth's scab over the period. Due to soaring carbon proportions, fossil fuel takes account of coal, oil, and natural gas. The carbon to hydrogen (C/H) ratios, composition varies like methane (CH₄), to oils. Non-volatile materials are made out of an unadulterated carbon, for example, anthracite coal (Liu *et al.*, 2015; Nick, 2009). In 2011, petroleum derivative utilization on the planet totaled eighty quadrillion British thermal units (Btu). The US Energy Information Administration (EIA) ball park reported that 80% of the vitality was imitative from non-renewable energy sources, particularly 35.3% arising of oil, 19.6% from coal, and 26.8% from petroleum gas. Nuclear power and sustainable power source represented 8.3% and 9.1%, respectively (Nick, 2009). Fossil fuels also known as non-renewable resources since they seize a long time to form and crude materials being dwindled substantially quicker than new ones. Fuel blazing generates more than 22 billion tons of CO₂ yearly, yet it is evaluated that typical techniques can just splash up about a portion of that quantity. This makes a net rise of 11 billion tons of barometrical CO₂ every year (Dandekar, 2005).

Coal

It is earth's most regarded common resources; it has been a source of heat and energy to the world for many years. Coal is formed due to decomposition of forest and other flora for several years. Coal essentially made up of carbon, while additionally containing components of hydrogen, oxygen, nitrogen, aluminum, silicon, iron, sulphur and calcium (Dandekar, 2005). Coal is the world's main profuse and broadly disseminated fossil fuel that fulfills more than one-fourth of essential energy demand worldwide (http://www.eia.gov/energyexplained/index.cfm?page=natural_gas_home). In the course of the last few decades, coal has out-paced by the use of gas, oil, atomic power, and renewable energy sources. North America, previously the Soviet Union, and the Asia Pacific United recorded more than 80% of set up coal holds. Worldwide coal creation in past decade topped 6.9 billion tons, with China delivering around 46%, the US 16%, and Australia and India measure up to makers at roughly 6%. 60% of coal is obtained using underground mining (<http://www.eia.gov/totalenergy/>). Coal-terminated power plants, presently, are confronting new difficulties inferable from an expanded challenge of petroleum and novel air toxin controls progressed by the EPA (<http://epa.gov/mats>). Regular CO₂ outflows from fuels control foliage are roughly two fold than that from natural gas plants (<http://epa.gov/mats>).

Petroleum

Petroleum, also known as crude-oil, consists of hydrocarbons and few biodegradable compounds in traces. It is obtained from the characteristic arrangements underneath Earth's surface. It is obtained through primitive natural materials, for example, algae and zooplankton. Oil is recouped generally from oil dreary. Due to the fast development of the car business leads to accessibility and contribution of gasoline (Gold, 2012; <http://www.epa.gov/climatechange/ghgemissions/gases.html>). Nowadays, petroleum is obtained in refined form and made its way into a scope of shopper items, including fuel (oil), lamp oil (paraffin), black-top (bitumen), and concoction ingredients required for plastics and pharmaceuticals manufacturing (<http://www.epa.gov/climatechange/ghgemissions/gases.html>). The term petroleum entirely alludes to the raw petroleum that incorporates all fluid, vaporous, and strong hydrocarbons. At typical conditions of temperature and pressure, lighter hydrocarbons including CH₄, ethane, propane, and butane subsisting gaseous state, while pentane (C₅H₁₂) and heavier organic compounds exist in liquids or solid state (Howell, 1979).

Because of the atmospheric conditions at the surface, these gases condense out to form natural-gas condensate. The quantity of lighter hydrocarbons present in petroleum varies from 97% (weight by weight) to merely 46% (Hunter *et al.*, 2005). Among Organization of Petroleum Exporting Countries (OPEC), the Five nations from Middle-East namely Iran, Saudi Arabia, Iraq, United Arab Emirates, and Kuwait, considered to have almost 70% of the aggregate oil holds in 2009, while lone Saudi Arabia claimed to have 26% of total OPEC reservoirs (http://www.eurekalert.org/pub_releases/2013-06/ultgt062013.php). Non-OPEC generation of oils is around 60% of the total global oil supply. China is emerging as the prevalent oil-overriding nation in the globe with a 7% annual growth rate. Worldwide petroleum utilization raised by 0.6 million barrels per day (b/d) in 2012, which is 88 million b/d. OECD utilization in-fact reduced by 1.2% corresponding to drift in recent past while Non-OECD utilization raised by 2.8% (<http://www.worldenergyoutlook.org/media/weo, 2010.pdf>).

Natural Gas

Natural gas originates in profound dissident innate rock pattern development or linked with trace hydrocarbon basins in coal reserves and as CH₄ catharses. As mentioned previously, oil is established in propinquity with natural gases well. Generally, natural gases were produced over a long period by biogenic or thermogenic means. Gas produced by biogenic means is resultant of the methanogenic activity of microbes (microbes that generates methane as a result of their metabolism in an anaerobic environment). Thermogenic gas is formed deep inside the earth at high temperatures and pressure from the dormant organic material (<http://dx.doi.org/10.1787/9789264095243-en>). Natural gas is frequently known as gas particularly in comparison with other available energy sources like coal or oil. A few decades back, natural-gas was acquired as a result of delivering oil. On the other hand, undesirable petroleum gas was parched in the oil field (<http://dx.doi.org/10.1787/9789264095243-en>).

The world's biggest gas reservoirs are situated in Russia having 48 trillion m³ of gas (Irby-Massie and Keyser, 2002). Russia is leading natural gas extractor worldwide. Erstwhile foremost verified resources of the natural gas exist in Iran, Qatar, Saudi Arabia, and the United Arab Emirates. The major gas field in the world is located in Qatar's North offshore. It is having approximately 25 trillion m³ of primed gas (<http://epa.gov/mats>).

Due to the over-exploitation of these resources, non-renewable sources of energy are vanishing rapidly. At the same time, its uncontrolled utilization is resulting in the huge growing concern of 'global warming' and increased 'greenhouse effect.'

Earth's Atmosphere and Greenhouse Gases

Changeability of climate is the greatest arguments and is the biggest apprehension nowadays for the human race. Advancement in studies of climate and meteorological research is well-known. Therefore, it is fitting to momentarily reconsider the writings of particular revolutionary consideration of previous centuries in consideration of the make-up of the atmosphere. In the 1820s, Jean Baptiste Joseph Fourier computed by the mass and distance from the sun; earth must have been significantly colder than in fact it is, considering the impact of inward solar waves (<http://www.whitehouse.gov/share/climate-action-plan>). The study by Jean Baptiste Joseph Fourier may be considered the most primitive scientific input of the greenhouse effect (<http://www.whitehouse.gov/share/climate-action-plan>). Four decades afterward John Tyndall recognized the irradiative nature of water vapor and CO₂ in controlling temperature of the surface (Rajaram, 2012). The study reported that humid air could soak up heat 13 times more than that of dry, purified air (<http://ocean.nationalgeographic.com/ocean/photos/sea-level-rise/>). Arrhenius became the first person to study the effect of doubling atmospheric CO₂ on overall climate and was honored with the Nobel Prize (1903) for Chemistry (<http://pubs.usgs.gov/circ/c1143/html/text.html>; Smith, 1997). Stretching out from earth's surface, the climate ensures life on earth by engrossing bright sun-powered radiation, warming the surface through temperature with-holding (the greenhouse effect), and diminishing temperature limits among day and night through a procedure called diurnal variety. The air comprised of 78.1% nitrogen, 20.9% oxygen, 0.9% argon, 0.04% carbon and little measures of different gases approximately (Rajaram, 2012). These different gases frequently alluded to as trace-gases, additionally contain the GHGs. GHGs can ingest and emanate radiation inside the warm infrared (IR) scope of the electromagnetic range of light (Stevens, 2012). The prime GHGs are water vapor, CO₂, CH₄, N₂O, and tropospheric ozone (Dandekar, 2005). Solar radiation short lived through the atmosphere which warms up the surface of the Earth. A portion of the energy comes back to the climate as long-wave warm radiation, some energy caught by the layer of

gases that encompasses the Earth, and the leftovers go into space. The fixation and a relative blend of these gases in the environment influence atmosphere dependability and changes in composition can result in climate change. Since the commencement of the modern transformation, human reliance on non-renewable energy sources, the release of mechanical synthetic concoctions, the reasoning of backwoods that would make some way or another assimilate CO₂, and their supplanting with animals farming, has changed the nature and amounts of gases in the atmosphere (http://www.chathamhouse.org/sites/default/files/public/Research/Energy,%20Environment%20and%20Development/bp_0812_stevens.pdf).

How Human Activities Produce GHGs

Generally, significant human actions emanate GHGs. Emissions are underway to ascend radically in the past centuries because of the industrial revolution and alteration in land use. Most of the GHG releasing actions are indispensable to the worldwide market and a crucial portion of the present existence.

CO₂ from blazing the fossil fuels is a major cause of GHG emanations from day-to-day activities. The utilization of fossil fuels contributes about 3/4th of CO₂ emanation, 1/5th of the CH₄, along with a noteworthy amount of N₂O (http://www.chathamhouse.org/sites/default/files/public/Research/Energy,%20Environment%20and%20Development/bp_0812_stevens.pdf). It gives rise to nitrogen oxides (NO_x), hydrocarbons (HC), and carbon monoxide (CO), which are not counted as GHG but persuades chemical reactions in an environment which gives rise to other GHGs, such as tropospheric ozone. For the meantime, fuel-related discharges of aerosols are momentarily making-up for the warming effect of GHGs (Rajaram, 2012).

The greater part of the GHG emissions is related to energy utilization resulting from the burning of fossil fuels. Oil, natural gas, and coal convey the majority of the energy used to deliver power, run cars, and power processing plants. If fuel consumed altogether, the main result controlling carbon would be CO₂ (Rajaram, 2012). However, most of the times burning is incomplete resulting in the emission of CO and other hydrocarbons. Nitrogen present in fuel gets combined with the oxygen which generates N₂O and other NO_x whereas, sulphur gets combine with oxygen to generate sulphur oxides (SO_x) (Smith, 1997).

GHG emissions take place through extortion, dispensation, transportation, and distribution of fossil fuels. These emissions can be conscious while flaring the natural gas, discharging mainly CO₂ and CH₄ (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf). Emissions likewise may result from mischance, poor support, and little breaks in well-heads, pipe fittings, and pipelines. CH₄ is taking place physically in coal and discharged when coal is pulverized. Hydrocarbons enter the atmosphere because of oil slicks from tanker boats or little misfortunes amid the routine fuelling of engine vehicles (Stevens, 2012).

The second largest source of CO₂ is deforestation. At the point when jungles were cleared for agricultural or industrial advancement, the vast majority of the carbon in the consumed or decaying trees breaks to the environment. In any case, when new backwoods are planted, the developing trees retain carbon dioxide, expelling it from the atmosphere (Turner and O'Connell, 2001). Late net deforestation has happened mostly in the tropics. There is a lot of logical vulnerability about emanations from deforestation, yet it is assessed that from 600 million to 2.6 billion tons of carbon are discharged all around consistently (http://www.chathamhouse.org/sites/default/files/public/Research/Energy,%20Environment%20and%20Development/bp_0812_stevens.pdf).

Lime production (calcium oxide) in cement manufacturing accounts for 2.5% of CO₂ emissions. CO₂ emissions are pre-dominant through cement manufacturing and principally from the biomass sector as well as sea-shell concealed in pre-historic marine sediments (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf).

Tamed creatures release of CH₄ which is another critical GHG after CO₂. CH₄ is formed from the excreta of the animals. Most domesticated animals related CH₄ emissions are resulting from the bacterial actions which cause fermentation of food in the digestive tracts of animals; while decomposition of animal manure also releases CH₄ (http://www.chathamhouse.org/sites/default/files/public/Research/Energy,%20Environment%20and%20Development/bp_0812_stevens.pdf). Livestock represents around one-fourth of the CH₄ discharges from human exercises, totaling somewhere in the range of 100 million tonnes a year (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf).

Rice cultivation additionally discharges CH₄, wetland or paddy rice cultivating produces approximately one-fifth to one-fourth of worldwide CH₄ outflows from human exercises. Representing more than 90% of all rice creation, wetland rice is developed in fields that are overflowed or flooded for a great part of the rainy season (Dandekar, 2005). Microorganisms in the dirt of the overwhelmed rice paddy break down organic compounds and emit CH₄ (Dandekar, 2005).

Disposal and treatment of waste additionally release GHGs. At the point when waste is disposed of in a landfill, it undergoes decomposition in prevailing anaerobic conditions and emanates CH₄. Except the gas is trapped and utilized as a fuel, the remaining CH₄, in the long run, disappears to the air. This CH₄ sink is more typical in urban communities, where rubbish from numerous homes is conveyed to the landfill than in rural areas where refuse is ordinarily burned or left to decay in the outside (<http://dx.doi.org/10.1787/9789264095243-en>). CH₄ is discharged additionally from the biological treatment of the sewage.

Excessive use of fertilizer results in emissions of No_x. The presence of nitrogen in a lot of fertilizers augments the bacterial action resulted in the nitrification and denitrification in the soil (http://www.eurekalert.org/pub_releases/2013-06/ultgt062013.php). The amount of N₂O emanated based on the nitrogen content of fertilizer and soil circumstances.

Chlorofluorocarbons (CFCs) are generally released from the industrial processes. Shaped in the 1920s, CFCs have been discharged in extensive amounts since 1950 (<https://www.epa.gov/nscep>). They have been utilized as charges in vaporized jars, in the fabricated of plastic froths for pads and different items. These are also used in the cooling curls of fridges and temperature control systems, as flame quenching materials, and also as solvents for cleaning. Most of the CFCs are used as a result of the

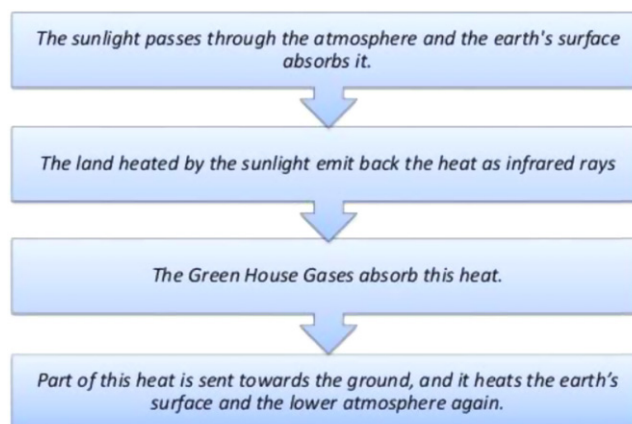

Fig. 1 The greenhouse effect.

Montreal Protocol on materials that reduce the Ozone Layer, barometrical centralizations of, e.g., CFC-11 have almost balanced out and are relied upon to decay over the coming decades. A few compounds being presented as CFC substitutes, for example, HCFCs, cause less harm to the ozone layer however these are yet powerful as GHGs (<https://www.epa.gov/nscep>).

Human activity has incredibly expanded the measure of GHG discharges in the environment. Rather than the worldwide impacts of ozone-depleting substances, the effect of anthropogenic pressurized canned products is limited principally toward the northern hemisphere, where the greater part of the world's modern action occurs. The example of increments in anthropogenic vaporized after some time is likewise fairly not the same as that of ozone-depleting substances. Amid the center of the twentieth century, there was a considerable increment in vaporized emanations. This seems to have been at any rate incompletely in charge of discontinuance of surface warming that occurred in the northern hemisphere during the 1940s to 1970s. Since that time, aerosols emanations have leveled off because antipollution measures were embraced in the industrialized nations since the 1960s. Vaporized discharges may ascend later on, nonetheless, because of the quick rise of coal-let go electric power age in China and India (<https://www.epa.gov/nscep>).

Greenhouse Effect

The greenhouse effect is a characteristic procedure that warms the Earth's surface. At the point when the Sun's energy reaches the earth's environment, some of it is replicated into space, and the rest gets absorbed by GHGs. The greenhouse effect in the atmosphere of the earth is depicted in [Fig. 1](#).

Most prominent GHGs can be listed as water vapor, CO₂, CH₄, N₂O, ozone (O₃) and some artificial chemicals such as CFCs. The engrossed energy heats the surface of the Earth. This course of warming upholds the Earth's temperature at around 33°C, favorable consent conditions for life on earth ([Smith, 1997](#)).

The Greenhouse Effect

The normal surface temperature of the planet is kept up by equalization of different types of sunlight based and earthbound radiation. Solar radiation is frequently called shortwave radiation because the frequencies of the radiation are moderately high and the wavelengths generally short – near the noticeable bit of the electromagnetic spectrum. Earthbound radiation, then again, is regularly called long-wave radiation because the frequencies are generally low and the wavelengths moderately long somewhere in the infrared piece of the range. Downward moving solar energy is typically measured in watts per square meter. The energy of the total incoming solar radiation is commonly estimated in watts per square meter. Modifying for the way that just a single portion of the planet's surface gets solar radiations, the normal surface insulation is 342 watts per square meter every year (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf).

The measure of sun-powered radiation consumed by the earth's surface is just a little part of the aggregate solar radiation entering the air. For every 100 units of approaching sun-based radiation, around 30 units are reflected back to space by cloud or intelligent areas of earth's surface (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf). This intelligent limit is alluded to as earth's planetary albino, and it requires not to stay settled after some time, due to the spatial degree and appropriation of intelligent arrangements, for example, mists and ice cover can change. The 70 units of sun based radiation that is not reflected might be consumed by the climate, mists, or the surface (<https://www.epa.gov/nscep>). Without further intricacies, to keep up thermodynamic harmony, earth's surface and air must emanate these equivalent 70 units back to space (<http://www.aip.org/history/climate/co2.htm>). Earth's surface temperature is joined with the scale of the emissions of outgoing radiation as reported by Stefan-Boltzmann law ([Turner and O'Connell, 2001](#)).

Earth's energy spending plan is additionally convoluted by the nursery impact. Follow gases with certain synthetic properties—the claimed GHGs, for the most part, CO_2 , CH_4 , and N_2O absorb a portion of the infrared radiation delivered by earth's surface. On account of this retention, some part of the initial 70 units does not specifically run away to space (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf). Since GHGs transmit a similar measure of radiation they retain and in light of the fact that this radiation is produced similarly every which way (that is, as much descending as upward), the net impact of ingestion by GHGs is to expand the aggregate sum of radiation discharged descending toward Earth's surface and lower climate (<http://www.aip.org/history/climate/co2.htm>). To look after balance, earth's surface and lower air must transmit more radiation than the initial 70 units. Subsequently, the surface temperature must be higher. This procedure isn't exactly the equivalent as that which oversees a genuine nursery, yet the end impact is comparable (<https://www.epa.gov/nscep>). The nearness of GHGs in the climate prompts warming of the surface and lowers some portion of the environment concerning what might be normal without GHGs.

It is basic to recognize the characteristic, or foundation, nursery impact from the improved nursery impact related to human movement. The common nursery impact is related to surface warming properties of regular constituents of the earth's environment, particularly water vapor, CO_2 , and CH_4 . The presence of this impact is acknowledged by all the researchers. For sure, in its nonattendance, earth's normal temperature would be colder than today, and earth would be a solidified planet.

In light of the article, evidence of the warmth of the earth's facade and beneath may be tailored in the following ways:

1. By a net increment in the sun oriented radiation entering at the highest point of earth's environment,
2. By an adjustment in the part of the radiation achieving the surface, and
3. By an adjustment in the grouping of greenhouse gases in the air.

For situation, the progressions can be thought of in regards to radioactive constraining. As defined by the IPCC (<https://www.epa.gov/nscep>), Irradiative compelling is a proportion of the impact of a given climatic factor on the measure of descending corresponding radiant energy impinging upon earth's surface. Climatic variables are isolated between those caused basically by human society and those caused by characteristic powers; at that point, for each factor, supposed constraining qualities are computed for the period among 1750 and the present day positive driving applied by climatic variables that add to the warming of earth's surface, while negative forcing applied by elements that cool earth's surface (<https://www.epa.gov/nscep>).

The Influences of Human Activity on Climate

Anthropogenic activities have a significant impact on the global temperatures by altering the radiative equilibrium leading the Earth on a variety of timescales and at shifting spatial scales. The anthropogenic activities are eminent in the increasing concentration. These activities influence climate change by altering the aerosols release and O_3 and thereby transforming the land cover pattern.

GHGs heat the surface of the earth by increasing the retention of long-wave radiations. The connection between air grouping of ozone-depleting substances and the related positive radiative driving of the surface is diverse for every gas. A confused relationship exists between the compound properties of every GHG and the relative measure of long-wave radiation that each can retain (<https://www.epa.gov/nscep>).

Water vapor is the most potent of the GHG in Earth's atmosphere, but its behavior is in a general sense not the same as that of the other GHGs. The essential role of water vapor isn't as an immediate specialist of radiative driving yet rather as atmosphere feedback that seems to be, as a reaction inside the atmosphere framework that impacts the framework's proceeded with activity. This distinction emerges from the way that the measure of water vapor in the environment can't when all is said in done, be specifically changed by human conduct, however, is rather set via air temperatures: the hotter the surface, the more prominent the dissipation rate of water from the surface. Accordingly, expanded dissipation prompts a more noteworthy centralization of water vapor in the lower climate equipped for engrossing long wave radiation and emanating it descending (<http://www.epa.gov/climatechange/EPAactivities.html>).

Some of the marine processes additionally go about as carbon sinks. One such process, called the solubility pump, involves the drop of surface seawater containing broke up CO_2 . Another procedure, the biological-pump consists of the take-up of broke up CO_2 by marine vegetation and phytoplankton (little free-skimming photosynthetic living beings) living in the upper sea or by other marine living beings that utilization CO_2 to assemble skeletons and different structures made of calcium carbonate (CaCO_3) (Smith, 1997). As these creatures' lapse and tumble to the sea depths, the carbon they contain is transported descending and, in the end, covered at profundity. A long haul balance between these regular sources and sinks prompts the foundation, or characteristic, level of CO_2 in the environment (Rajaram, 2012).

Conversely, human exercises increment air CO_2 levels basically through the consumption of fossil fuel principally oil and coal and optionally gaseous petrol, for use in transportation, warming, and the age of electrical power and through the creation of bond (<https://www.epa.gov/nscep>). Other anthropogenic sources incorporate the consuming of backwoods and the clearing of land. Anthropogenic discharges at present record for the yearly arrival of around 7 billion tons of carbon into the air. Anthropogenic emanations are equivalent to around 3% of the aggregate outflows of CO_2 by characteristic sources, and this increased carbon stack from human exercises far surpasses the counterbalancing limit of regular sinks (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf).

CO₂ subsequently aggregated in the air at a normal rate of 1.4 sections for every million by volume (ppmv) every year somewhere in the range of 1959 and 2006, and somewhere in the range 2007 and 2017, the rate of CO₂ gathering expanded to around 2.25 ppmv every year (<http://www.eia.gov/totalenergy/>). Considering the entire dataset, the development in air carbon focuses has been genuinely straight. However, this could change. A certain flow sinks, for example, the seas, could move toward becoming sources later on. This may prompt a circumstance in which the centralization of environmental CO₂ works at an exponential rate (Rajaram, 2012).

The regular foundation level of CO₂ fluctuates on timescales of a great many year's given moderate changes in out-gassing through volcanic action. For instance, about 100 million years back, amid the Cretaceous Period (145 million to 66 million years prior), CO₂ fixations seem to have been a few times higher than they are today (maybe near 2000 ppm) (<http://epa.gov/mats>). In recent years, CO₂ fixations have fluctuated over a far littler range (between around 180 and 300 ppm) in a relationship with a similar Earth orbital impacts connected to the traveling every which way of the Pleistocene ice ages (see underneath Natural effects on atmosphere) (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf). In 2017 CO₂ levels achieved 403 ppm, or, in other words, percent over the characteristic foundation level of about 280 ppm that existed toward the start of the industrial revolution (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf). According to ice core measurements, this level (403 ppm) is believed to be the highest in at least 800,000 years and, according to other lines of evidence, may be the highest in at least 5 million years (Turner and O'Connell, 2001).

Methane

CH₄ is another largely significant GHG. CH₄ is more intense than CO₂ because the radiative compelling delivered per particle is greater. In any case, CH₄ subsists in lower fixations as compared to CO₂ and focuses by volume and large estimated in ppb as opposed to ppm (<http://dx.doi.org/10.1787/9789264095243-en>). CH₄ additionally has an impressively shorter habitation time as compared to CO₂ yet having 23 times more global warming potential than CO₂ (<http://www.epa.gov/climatechange/ghgemissions/gases.html>).

Common sources of CH₄ include tropical wetlands, anaerobic microorganisms that nourishes on natural material. These microbes releases CH₄ as a natural residue, and CH₄ leaks from the mainland racks of the seas and polar permafrost. The essential regular sink for methane is simply the climate, as CH₄ responds promptly with the hydroxyl radical (OH) inside the troposphere to frame CO₂ and water vapor (<http://www.epa.gov/climatechange/ghgemissions/gases.html>). At the point when CH₄ achieves the stratosphere, it is devastated. Bacteria present in soil can also be brought the CH₄ oxidation. The overall methane cycle is shown in Fig. 2.

Alongside CO₂, human action is expanding the CH₄ fixation quicker than it may be balanced by regular sinks. Anthropogenic sources as of now represent around 70% of yearly discharges, prompting generous increments in fixation after some time (<https://www.epa.gov/nscap>). The major anthropogenic wellsprings of environmental CH₄ are development in rice cultivation, domesticated animals cultivating, the consuming of coal and gaseous petrol, the burning of biomass, and the disintegration of a natural issue in landfills (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf). Future patterns are especially hard to anticipate. This is to some extent because of an uneven knowledge of the atmosphere inputs related with CH₄ outflows. Likewise, it is hard to anticipate how human populaces develop, conceivable changes in domesticated animals rising, advancement in rice cultivation, and vitality usage will impact CH₄ emanations (<http://www.aip.org/history/climate/co2.htm>).

The Environmental Challenge

CH₄ and CO₂ are discharged both from landfills, and agricultural sectors which ultimately results in climate change. Sustainable ways for its safe and ecologically stable transfer is a noteworthy test for large-scale agricultural practices. Utilizing petroleum derivatives for vitality adds to a dangerous atmospheric deviation, and vitality needs are developing in numerous nations. Catching waste gases and changing over them to vitality can relieve environmental change by bringing down the utilization of petroleum derivatives, in the meantime diminishing the arrival of hurtful gases. As indicated by the United Nations Environment Program (UNEP, 2011), with the end goal to guarantee the normal worldwide temperature does not ascend by more than 2°C by 2020, the level of essential vitality that is created from non-petroleum derivative vitality sources, for example, biogas, should increment by as much as 28% by 2020 (Dandekar, 2005).

Mitigation of Greenhouse Gasses

The awareness of GHG and their potential harm have been known for along time. In the nineteenth century, researchers understood that gases in the environment cause greenhouse effect which influences the temperature of the planet. The researchers were interested mostly in the probability that a lower level of CO₂ gas might explain the ice times of the disconnected past. When the new century rolled over, Svante Arrhenius figured out that emanations from human industry might sometime bring a global warming. He found that the gas assumes an essential job in environmental change with the goal that the rising level could gravely influence our future (http://www.pseg.com/info/media/newsreleases/2011/attachments/njclean_air_council10-12-2011.pdf).

Fig. 2 Flow chart: methane cycle.

China is currently the leading culprit of producing excessive CO_2 . Before China; the United States had been the most significant contributor to the problem; hence the United States government has taken strides to tackle this issue. For example, on June 25, 2013, President Obama announced a plan to continue to reduce carbon emissions and to expedite resolutions for GHGs. The United States has made efforts through the EPA ([Environmental Protection Agency, 2013](http://www.epa.gov/climatechange/ghgemissions/gases.html)) to address the problem; these include collection emissions data, getting reductions, evaluating policy options, costs, and benefits, advancing the science, partner in an internationally, partnering with states, localities, and tribes, and helping communities adapt (<http://www.epa.gov/climatechange/ghgemissions/gases.html>).

It is encouraging to see that steps are being taken to mitigate greenhouse gasses both nationally and internationally and to try to reduce the harmful consequences that already exist. Unfortunately, the beneficial progress continues to meet resistance. A factor that usually causes such delays is the motivation to persuade people to participate. Therefore, it is proposed to mitigate GHGs by converting the GHGs into energy (http://pubs.usgs.gov/circ/c_1143/html/text.html). Energy is an easy conversion into money, and economic gain is a great motivator. By converting GHGs into energy, we can remove the existing excess GHGs and capture the newly-produced gasses, and in turn profit from the mitigation of these gasses. The profit generated would hopefully be an incentive to motivate action.

Utilizing Greenhouse Effect as a Source of Energy

While the human race will always leave its carbon footprint on the Earth, it must continue to find ways to lessen the impact of its fossil fuel consumption. There has been growing interest over recent years regarding the carbon capture and utilization (CCU) in GHE mitigation (<http://www.worldenergyoutlook.org/media/weo2010.pdf>). Despite its potential, their significant uncertainties persist with regards to CCU's ability to achieve real and measurable emissions reductions within carbon reduction support schemes (<http://www.worldenergyoutlook.org/media/weo2010.pdf>).

Carbon capture advances: one approach is to catch CO_2 synthetically before its discharge into the environment. Research conducted in Cornell University uncovers new approach for capturing GHGs transforming it into a valuable item along with the electrical supply. Nowadays the majority of CCU models utilizes liquids (as fluids), followed by vaporization or depressurization to discharge CO_2 (Howell, 1979). The resolute gas can be packed for transportation, and various ventures can reuse it readily, or subjected to underground sequestration. The discoveries in investigation speak to a conceivable change in perspective (**Fig. 3**).

Fig. 3 Utilizing GHGs as energy.

A novel way of generating fuels like gasoline, jet fuel, and diesel from CO₂ can be attained by the new catalyst. Adaptation of such technology for conversion of CO₂ into fuel at large scale can solve the predicted energy crisis shortly. This novel technology can also be worked on the existing facilities of energy storage and transportation without any net GHG emissions to the environment (<http://www.aip.org/history/climate/co2.htm>).

The innovative approach like using porous silver electrode which can be able to transform CO₂ and water into CO and hydrogen is also being practiced. Transforming CO₂ into CO itself is the biggest achievement in the utilization of GHG for producing energy and other value-added products (<http://www.epa.gov/climatechange/EPAactivities.html>). Presently, CO and Hydrogen mixture is used widely as a source of energy. The major issue of CO₂ transformation is its selective conversion to yield and hydrogen in the required amount which can act as a precursor for further chemical processing. The unique system hence developed will provide the selective and specific pathway for CO₂ to CO conversion. Desired CO proportion can be obtained in the system through the modifications in the meso structure of the porous material (<http://www.epa.gov/climatechange/EPAactivities.html>).

A Cell Full of Water, Air, and CO₂

An innovative fuel cell utilizing air water and CO₂ (composite air) is proving to be the best energy source using GHGs. The advancement was attained with modification in fuel cells and adaptation of a capacitive electrochemical cell. A battery like an assembly of this cell is provided with two porous electrodes: anode which attracts H⁺ ions, and a cathode that attracts the bicarbonate ions. The inflow in the cell was maintained by bubbling CO₂ in the water (<http://www.epa.gov/climatechange/EPAactivities.html>). Initially, this CO₂-packed water is pumped through the cell which results into the increased flow of each ion from the water towards cathode and anode – the ion-flow results into the charge separation that creates the potential to drive an electrical current. In a later stage where maximum ions are absorbed by the electrodes, air is bubbled into the water that leads to the backflow of ions from electrodes to the cell. Due to the continuous alternation of these processes the cell can provide continuous electrical supply (<http://www.aip.org/history/climate/co2.htm>).

Making the Mix

This concept is evolved from the released energy of fluids (e.g., with different densities) when mixed in an appropriate ratio. This fundamental material science idea holds for the two gases and fluids, however, till date; no innovation existed for adequately harvesting the energy released from mixing of fluids like (Hydrogen & CO) (<http://epa.gov/mats>). It can help in developing the relatively simple and cost-effective technology which could present an energy source with an aggregate yearly (worldwide) limit of 1570 TWh (terawatt hours) potential (<http://epa.gov/mats>).

When Researchers and policymakers are in search of the permanent solution to reduce this GHG and its adverse impacts, the shift in the trends of global research to figure out a way to use GHG for generating renewable energy and it seems the study can provide a sustainable solution to the alarming issue of GHG emissions and greenhouse effect (<http://epa.gov/mats>).

Methane Capture and Utilization

Landfills and tropical wetlands are reportedly the significant sources of CH₄ emissions. CH₄ is a major GHG found in the environment. CH₄ can be used as fuel because of CH₄ capture and utilization to produce electricity, heat buildings, or power garbage trucks. Landfills are the major source of CH₄. Confining CH₄ prior to the release into the atmosphere can be the key to

reduce the effects of CH₄ on climate change (<http://www.aip.org/history/climate/co2.htm>). CH₄ capture from ranch digesters that are large cisterns that restraint with household waste (biodegradable) along with cattle. Thousands of landfill-to-energy projects are presently functional across the globe, and many more landfills can also be considered to harvest methane and convert it into a suitable form of energy. If the total energy balance is taken into account, overall methane being produced from the landfills will generate electricity which concurs the need of 688,000 households per day (<http://www.aip.org/history/climate/co2.htm>).

These technologies cannot be termed as 'renewable energy technology' at least in the very long-term, but these technologies are perhaps cleaner, and certainly adaptation of these novel cleaner technologies will definitely play a vital role in GHE reduction targets in coming years.

Conclusions and Perspectives

By providing a succinct source of information about GHGs, and the resulting harmful effects caused along with the significance of their mitigation will produce the motivation to decrease these gasses by transforming them into a beneficial energy source.

Detailed cost-benefit analysis and economic profile of the various ways to alleviate the greenhouse effect needs to systematically and succinctly comply, so that a logical way for implementation of the processes can be chalked out. The combination of this initial information and financially-focused study will hopefully motivate the performance of GHG generated energy. The performance of greenhouse generated energy will develop the job prospects in a newly invented commercial market, which will be ecological and economically advantageous. At the same time, these energy companies will be extenuating the existing greenhouse effect and avert any dangerous auxiliary consequences. It is a win-win situation for the earth and mankind.

Glossary

Micro-siting Process of choosing the type of wind turbine and its exact position

Plant load factor Output of a power plant compared to the maximum output it could produce

Re-powering Process of replacing older power stations with newer, more efficient ones

Wind power density A quantitative measure of wind energy available at any location

Introduction

Energy is an enabling medium for economic development, technological advancement and a necessary factor for production. The need for energy and its related services to satisfy human social and economic development, welfare and health is increasing. But there are many regions in the world with a limited accessibility to grid based electricity due to economic, geographic and other factors making conventional grid unviable. Turning to renewable energy sources is an excellent approach which needs to be sustainable in order to meet energy demand of future generations. Since they are obtained naturally from ongoing flows of energy in our surroundings, they are considered clean sources of energy. Optimal use of these resources decreases environmental impacts, produces minimum secondary waste and provides non-harmful delivery of environmental goods and services. Also these resources are limitless and thus sustainable based on the current and future economic and social needs.

Considering that the major component of greenhouse gases is carbon dioxide, there is global concern to reduce carbon emissions. In this regard, different policies could be applied to reduce carbon emissions, such as enhancing renewable energy deployment and encouraging technological innovations. Renewable energy technologies provide an exceptional opportunity for mitigation of greenhouse gas emission (like CO₂) and reducing global warming through substituting conventional energy sources (fossil fuel based).

Greenhouse gases (GHGs) concentrations in the earth's atmosphere need to be limited to mitigate significant changes to natural systems which in turn could effect resource use, production & economic activities. Identifying & then reducing the sources of emission relies on proper assessment, monitoring and verification of GHG emissions and removals of which carbon footprint is an important element. A carbon footprint relates to the amount of GHGs produced through burning fossil fuels for electricity, heating and transportation etc. It calculates the volume of the produced greenhouse gases in CO₂ equivalents for any particular activity; which is used to compare the greenhouse gas emissions between companies, institutions and other bodies. Then appropriate reduction measures can be considered and introduced like the use of green energy sources, reduction of fossil fuel consumption, appropriate waste management and recycling to save material cost and energy.

Among the green energy sources, wind energy has great potential to reduce GHG emissions resulting from energy services. Also, wind energy has a comparatively small environmental footprint when relative impacts of various energy supply technologies are measured. Repowering in wind energy has significant potential in this regard and contributes to a more secure energy supply. Along with reduced GHG emissions, it provides additional environmental benefits depending on the advanced technology, management and site characteristics of the proposed wind farm for repowering project. Though average wind speeds in different locations vary considerably, enough technical potential is there in most parts of the world for significant use of wind energy. Repowering further reduces the cost and improves wind energy's footprint reduction potential. Wind energy has taken a commanding lead among other renewable energy sources. Wind exists everywhere in the world, in some places with considerable energy density which can be harnessed by means of kinetic energy from moving air. The primary application is to produce electricity from large turbines located onshore (land) or offshore (in sea or fresh water). Production of electricity using wind energy saves a considerable amount of CO₂ emission which may be discharged in the environment if the same power is generated using conventional sources of energy.

Recent developments in technology open new pathways to creating more power. Re-powering is one of the methods to increase the total available power of existing wind farms. It means replacement of installed old wind turbines of lower capacity by modern turbines of higher capacity normally in lesser numbers. It also refers to replace first generation turbines installed for more than twenty years back. It has generally been accomplished by installing fewer, larger capacity turbines. The modern commercial grid connected wind turbines are multi-megawatt machines equipped with advanced operation and control systems. As per a study carried out at Riso Laboratory, Denmark, the process of re-powering will double the capacity and triple the energy yield with half the infrastructure. Another report of Leonardo Energy outlines the repowering program for following factors (Verma *et al.*, 2015):

Fig. 1 Wind farm at Jamgodrani Hills, Madhya Pradesh, India.

- Without adding more land to the wind farm its capacity can be multiplied which gives more annual energy production from the same site and land area.
- Reduction in cost of per unit generation due to higher efficiency of individual turbines.
- Better grid integration due to improved power electronics.
- Appearance of the landscape is improved due to fewer wind turbines than earlier. The hub height is also increased after repowering.
- Better prediction of wind characteristics and annual energy generation of an existing site.
- Visual appearance is better as modern wind turbines rotate with lower rotational speeds. (Figs. 1 and 2).

Indian Scenario

According to Indian Wind Energy Institute the gross wind power capacity in the country is estimated to be about 49 GW at 50 m elevation and 102 GW at 80 m elevation with the assumption of 2% land availability. The installed capacity of wind power is more than 32 GW up to February 2018 (Central Electricity Authority Report-2018). It contributes more than 50% of total renewable energy capacity of the country. More than 90% of wind power potential is concentrated in southern and western states like Tamilnadu, Karnataka, Andhra Pradesh, Maharashtra, Gujarat and Rajasthan. Wind energy development in India started in early 1990s and the wind farms were developed in the areas where the wind regime is often very good. Therefore, the old or first generation wind turbines occupy the best windy locations. These turbines are also of lower hub height (about 30–40 m), lower capacity and lower efficiency and fitted with old technology in terms of generator, control mechanisms, power quality etc. These sites with the best wind can be utilized more efficiently by replacing old turbines by modern machines of hub height of more than 80 m. New locations for wind farms are becoming scarcely available due to non-availability of useful land, environmental protection, green belt requirements and sometimes resistance from the local populace. Re-powering can contribute to achieve national target of achieving installed capacity of 100 GW by year 2022 under National Mission for Wind Energy of Ministry of New and Renewable Energy, Government of India. It also contributes to reducing the level of CO₂ emission. In India about 25% of the old installed turbines have rating below 500 kW of the total installed capacity to date which is in the order of 22,000 MW. Most of these turbines are hardly in efficient working conditions. It offers a great opportunity and huge technical and economical challenge to replace roughly 5500 MW capacity of old turbines. Re-powering priority is to be given for wind farms with a plant load factor (PLF) less than 12% (Ahmed, 2015; Sharma *et al.*, 2012).

Issues and Challenges

Wind turbines are generally designed for a service life of 20–25 years. After replacement due to re-powering, the old turbines are usually not installed on the same site. These can be sold for installation at some other location for their remaining service life or

Fig. 2 Topo sheet of Jamgodrani Hills. Source: Survey of India, Jabalpur.

can be sold for scrap for recycling of different parts. Turbines are placed in rows in a wind farm, typically perpendicular to prevailing wind direction by micro-siting process involving flow modeling, micro surveys and wind monitoring and by determining array efficiency and turbulence in the downstream (Verma *et al.*, 2016; Goyal, 2010).

There are many challenges for re-powering such as:

Turbine ownership: More numbers of turbines are replaced by fewer numbers due to which the matter of ownership becomes an issue to be resolved in cases where one to one replacement is not possible.

Land ownership: There is an issue of multiple ownership of wind farm land to be resolved.

Power purchase agreement: PPA might have been signed for long duration, before the end of which re-powering may pose difficulties.

Electricity evacuation: Enhanced power output due to re-powering may require modification or replacement of current equipments and systems of the grid as it is designed to handle current power supply.

Additional cost: The decommissioning cost of existing turbines is to be estimated.

Disposal of existing turbines: Many options for disposal of old, to be replaced turbines are to be analyzed like scrap value, buy-back by manufacturer, relocation cost etc.

Re-Powering Approach

There are certain technical aspects to be considered to determine the re-powering potential of an existing wind farm site:

- Characteristics of the wind resource of the site are to be studied such as speed frequency distribution curve of past several years, Weibull parameters, wind power density, turbulence intensity, power law index, wind rose, prevailing wind direction etc.
- Everything about the existing wind turbines is considered like the number of turbines, their capacity, power curve, cut-in, rated and cut-out speed, rotational speed per minute, hub height, type of generator, rating, thrust and power coefficient etc.
- Proposed modern wind turbine, its capacity and detailed specifications are to be analyzed.
- Available area with necessary off-set from approaching roads and dwellings is to be determined.
- Estimation of annual energy production, gross and net energy production and array efficiency from proposed re-powering turbines at new hub height is to be done.
- Proper planning of proposed wind turbines with micro-siting and turbine array spacing is to be done.
- Re-powering ratio of proposed turbines to existing turbines is to be determined first.

- Energy yield ratio of proposed turbines to existing turbines for same site or area is to be calculated.
- Dismantling cost of existing wind turbines, cost of installation and commissioning of new turbines, unit cost of energy after re-powering and cost of other modified facilities is to be included in the overall economic analysis.

In the next 10 years, it is expected that off-shore wind farms will be developed in select wind zones on Indian Ocean and Arabian Sea. These wind farms will be repowered in next 15–20 years in future. Therefore it requires master plan approach to make the re-powering process a dynamic exercise (Karoui *et al.*, 2017).

High capacity wind turbines are particularly well adapted for sites with higher average wind speeds. Report of Leonardo Energy outlines that: For utilities trying to scale-up their capacity to achieve set target put preference for larger wind turbines. The practical reason is that power output of a wind turbine is depending on square of rotor diameter therefore larger wind turbine is better than two smaller wind turbine of same capacity. The larger wind turbines are preferred for off-shore applications as it minimizes installation cost per MW in terms of foundation cost which takes significant proportion of total cost of installation.

Need for Repowering

Development of the wind power projects in India started off more than two decades ago, and thousands of mega-watts of new capacities are being added on every year. Thus one can find plenty of wind farms that have operated for more than 12 years by now. The turbines that have been installed in these old farms have either already completed their service lives or are nearing the end of it; however generation should continue further and possibly increase in the future. Given the worn out turbines, the generation is likely to drop, and thus, the project developers are now facing with end-of-life decisions. Now during these decades technology has gone ahead big time, and today not only has the hub heights, but also the efficiencies of the turbines doubled. The old PPAs also have either ended or are nearing the end dates. The solution to this issue is repowering (Indian Wind Turbine Manufacturers Association IWTMA, 2015; Tripathi, 2017).

The main salient features of the repowering policy are enumerated as follows:

- As part of the policy, wind turbine generators of capacity 1 MW and below will be eligible for repowering.
- Indian Renewable Energy Development Agency will provide an additional interest rate rebate of 0.25% for repowering projects.
- Benefits available to the new wind projects, that is, accelerated depreciation or Generation Based Incentives (GBI) as per applicable conditions will also be available.
- In case augmentation of transmission system from pooling station onwards is required, the same would be carried out by the respective state transmission utility.
- Additional generation could either be purchased by Distribution Companies at feed-in-tariff applicable in the state at the time of commissioning of the repowering project or allowed for third party sale.

Techno-Economic Analysis

Flow modeling requires three essential set of technical data related to wind, site and turbine:

- Wind characteristics
- Site characteristics, and
- Wind turbine characteristics

Wind Characteristics

For the development of wind energy, the site characterization has to include following major parameters and information: Annual average wind speed (WAsP requires the wind data measured at 10 min intervals by a meteorological mast in the same region), wind power density, wind rose, wind resource map, prevailing wind direction, speed frequency distribution and persistence, vertical wind speed profile, wind shear exponent, Weibull shape parameter (k), scale parameter (c), turbulence intensity, wind density and its variation vertically and seasonally, historical wind data (including frequency and intensity of past storms) etc.

Site Characteristics

Location (latitude, longitude and mean sea level), topographic maps provide the analyst with a preliminary look at site attributes, including available land area, contour map, roughness class of the site, grid related data, transmission line map, positions of existing roads and dwellings, land cover (e.g., forests), political and administrative boundaries, parks, national parks, forest reserves, restricted areas, proximity to transmission lines, location of significant obstructions, potential impact on local aesthetics, cellular phone service reliability for data transfers, other infrastructural facilities.

Fig. 3 Research Site location. *Source:* Maps of India.

The Jamgodrani wind farm is located in district Dewas of state Madhya Pradesh in central India. The geographical coordinates of the farm is latitude of 22° 59' 9", longitude of 76° 9' 5 6.5" and at an altitude of 580 m from the sea level. The factors which may impact the characteristics of wind are urban cities Indore and Ujjain which are closest to the wind farm and the Kshipra River. The wind farm covers an area of approximately 12,000 sq m which has non-uniform surfaces and contains a number of small water pools, farm lands and some manmade developments as shown in Fig. 3.

Wind Turbine and Farm Characteristics

Wind farm layout of existing and after re-powering, power and thrust curve of the turbine(s), hub height, rotor diameter, pitch mechanism, braking mechanism, generator type, gear or gearless machine, type of power electronics, cut-in, rated and cut-out speeds, capacity factor etc (Figs. 4–6).

In addition to above, the parameters related to machine availability, grid availability, transmission losses and WAsP prediction error is to be considered for arriving at annual energy production value. The annual energy production (AEP) of the wind farm after re-powering can be predicted by using industry standard WAsP (Wind Atlas Analysis and Application Programme) and simulation can be performed by using MATLAB. Following parameters are to be determined after analysis for re-powering (Ganesan and Ahmed, 2008; Diwakar *et al.*, 2010):

- Improvement in plant load factor (PLF),
- Increase in annual energy production (AEP) or energy yield,
- Increase in installed capacity of wind farm,
- Change in reactive power consumption.

Wind power density

Wind power available per unit area swept by the turbine blades is called as Wind Power density.

Where,

$$\text{Wind Power Density} = \frac{1}{2n} \sum_{i=1}^n \rho V_i^3 \quad (1)$$

n = number of records in averaging interval

ρ = air density (kg/m³),

v = wind speed value (m/s)

Fig. 4 Contour Map of Jamgodrani Hills.

Fig. 5 Existing Research Site location at Jamgodrani Hills. Source: Google Earth Image.

Fig. 6 Proposed Research Site location at Jamgodrani Hills.

Power law equation

$$\frac{V_2}{V_1} = \left(\frac{Z_2}{Z_1} \right)^\alpha \quad (2)$$

Where,

V_2, V_1 = wind speeds,

Z_2, Z_1 = heights,

And α = power law index or empirical wind shear

Where,

$$\alpha = \frac{\log \frac{V_2}{V_1}}{\log \frac{Z_2}{Z_1}} \quad (3)$$

Energy production analysis

The theoretical maximum annual energy production is given by

$$AEP_{max} = \frac{(R \times N \times 24 \times 365)}{1000} kWhr \quad (4)$$

While the actual annual energy production is given by

$$AEP = \left(\sum_{m \in M} W(m) \times P(m) \right) \times \frac{N \times 24 \times 365}{1000} kWhr \quad (5)$$

Where,

R = Rating of turbine.

N = Number of turbines.

W = Weibull distribution.

P = Power curve of turbine.

Weibull distribution

The Weibull is a two parameter distribution function and is represented by a dimensionless shape parameter k and scale parameter c in units of wind speed (m/s) and it can be described by its probability density function $f(v)$ and cumulative distribution function $F(v)$ as given below:

$$f(v) = \frac{k}{c} \left(\frac{v}{c}\right)^{k-1} \times \exp\left[-\left(\frac{v}{c}\right)^k\right] \quad (1')$$

$$F(v) = 1 - \exp\left[-\left(\frac{v}{c}\right)^k\right] \quad (2')$$

Where v is the wind speed, k is the dimensionless shape parameter, and c is the scale parameter having the same unit as v (m/s). The distribution is termed as Rayleigh distribution when its shape parameter k is 2. For calculating the parameters of the Weibull distribution nine different numerical methods are used in this study (Diwakar *et al.*, 2010).

Actual Methodology for Proposed Research Work

- (1) Select the research site.
- (2) Collect the wind data from National Institute of Wind Energy from Chennai, Tamilnadu.
- (3) Extrapolation of data at different heights to optimize the results.
- (4) Replacing existing wind turbine with new modern wind turbines.
- (5) Analysis of site (Jamgodrani Hills) by meteorological data.
- (6) Draw wind rose pattern of the research site using WAsP software and MATLAB software.
- (7) Evaluate and analyze technical data of research site with economical study.
- (8) Compare current technical data with modern wind turbines data to enhance the efficiency and net increase power generation through repowering.

Data Interpretation Through WAsP and MATLAB

WAsP Based Software Analysis

WAsP (Version 8.0) is a complete software package for wind data analysis, map editing, wind atlas generation, wind resource assessment and siting of wind turbines. Working with wind resource assessment and WAsP in practice, however, requires other software as well.

In 1987 the Wind Energy and Atmospheric Physics Department at Riso National Laboratory introduced WAsP – A powerful tool for wind data analysis, wind atlas generation, wind climate estimation and siting of wind turbines.

MATLAB Based Software Analysis

MATLAB (Matrix Laboratory) is basically a high level language which has many specialized toolboxes for making things easier. MATLAB allows matrix manipulations, plotting of functions and data, implementation of algorithms and creation of user interfaces

- WAsP Version: 8.0
- MATLAB Version: R2012b

Data Interpretation Through WAsP and MATLAB

Roughness effect, Orographic effect, power density curve for individual turbines are analyzed for existing wind turbines using WAsP software as shown in Figs. 7–9.

Roughness effect, Orographic effect, power density curve for individual turbines are analyzed for proposed wind turbines using WAsP software as shown in figures below. Wind rose distribution and probability distribution function (PDF) at 20 m height in WAsP is also drawn to obtain wind rose pattern and predominant wind direction of the research site (Figs. 10–12).

Wind Speed Probability Distribution Function (PDF) and Weibull Cumulative Distribution Function (CDF) at different heights (30 m and 80 m) are plotted through MATLAB based programming to obtain the probability and wind flow distribution of existing and proposed site of Jamgodrani hills as shown in Fig. 13.

Results and Discussions

Re-Powering Outcomes

The analysis shows that the repowering can increase the capacity utilization factor from 12.26% to 22.61% hence about 10% boost could be achieved.

Fig. 7 Roughness effect on existing wind turbines using WAsP.

Energy Production Analysis

See [Table 1](#).

Cost Analysis

Considering the tariff of 4.35 INR per units with no escalation for 25 years the repowered wind farm can be recovered within

$$\frac{1050000000}{27716640} = 8.7 \text{ years}$$

The payback period/recovery can be further decreased by considering the reselling of old turbines, finance rate and the government subsidies ([Table 2](#)).

Fig. 8 Orographic effect on existing wind turbines using WAsP.

Environmental Analysis

The repowering causes a significant reduction in the total number of wind generators from 58 to 7, which are also located at much greater heights. This greatly reduces the visual and acoustic impact.

Suggestions and Recommendations With Possible Solutions (for a Case Study in Southern Region of India)

The study identifies key challenges which are likely to be faced by the re-powering project in Muppandal region of Tamil Nadu State. Following are the key challenges and their possible solutions:

New Power Purchase Agreements (PPA)

For sale to Executive Board (EB) projects, many if not most of the projects are under the old PPA rates and in case the projects are to be set up by dismantling of old Wind Turbine Generators (WTG), it is recommended for financial viability of the projects that

Fig. 9 Power density on existing wind turbines using WAsP.

Tamil Nadu Generation and Distribution Corporation Limited (TANGEDCO) should allow developers to sell power under current FiT (Feed in Tariff) rates. It is possible TANGEDCO will not be willing to come out of such PPAs where they are buying power at much cheaper rate than that of current tariff. Few of the existing project proponents may have a PPA with private consumers (industrial/commercial) at the indexed tariff, who will not be willing to come out of the existing short term PPA because of power deficiency in the state. But since the Third-party sale rates are very high, PPAs should be allowed to lapse after giving a notice of six months which will give existing power buyers the required time to find new sellers.

Possible solution

There should be a provision of “Right of First Refusal to Purchase” to the existing group of captive PPA holders to buy power from the repowered projects at competitive rates. In this case the existing power purchaser should have the right to opt the electricity generated from repowered project at the price determined by the state regulatory body and if existing purchaser refuses to opt then only power producer may opt to go for other option of sale of electricity. This way interest of existing power purchaser will be safeguarded. In another option each repowered project can be considered as a new project in terms of PPA rates and the existing PPA should lapse with a notice period of 6–12 months.

Fig. 10 Roughness effect on proposed wind turbines using WAsP.

Turbine and Project Ownership

Multiple owners of wind farm land may create complications for repowering projects in terms of obtaining permission. The wind turbines are maintained by different agencies and Original Equipment Manufacturers (OEM). Repowering will reduce the number of turbines and there may not be one-to-one replacement. Thus, the issue of ownership needs to be handled carefully.

Possible solution

It is necessary to identify and engage concerned stakeholders such as owners of the wind farms, OEMs, project developers, financial institutions, regulatory bodies, nodal agencies, land owners, operation and management agencies etc. to arrive at a workable business model. All existing stakeholders willing to re-power can be made partners in a Special Purpose Vehicle (SPV) company and profits can be shared in the ratio of equity shareholding in the SPV.

Disposal of Wind Turbine

The disposal of the old WTG is an important factor which is a challenge in itself for repowering projects.

Fig. 11 Power Density on proposed wind turbines using WAsP.

Possible solution

There are various options such as scrapping to recycle usable parts, buy-back by the government or manufacturer and reusing at some other location. Local capacity may need to be developed. But most of the turbines may be too old and in unusable condition and can be just sold as scrap to be scavenged for usable spare parts, copper and other expensive metals.

Incentives

One of the primary barriers of re-powering is the general lack of economic incentive to replace the older WTGs.

Possible solution

Appropriate incentives are necessary in order to compensate for the additional cost of re-powering. To encourage repowering, financial incentives need to be extended by the Government. The following are some of the incentives which can boost repowering in the country.

Fig. 12 Wind rose distribution and probability distribution function (PDF) at 20 m height in WASP.

(a) Wind speed function at 30 meter height

(b) Wind speed function at 30 meter height

(c) Wind speed function at 80 meter height

(d) Wind speed function at 80 meter height

Table 1 Energy production analysis

<i>Before repowering</i>		
<i>Parameters</i>		
a.	Annual Energy Production (AEP)	114.186 <i>GWhr per year</i>
b.	The actual Annual Energy Output is	14.003 <i>GWhr per year</i>
c.	Capacity Utilization Factor (CUF) [c = b/a]	12.26%
AFTER REPOWERING		
<i>Parameters</i>		
a.	Annual Energy Production (AEP)	122.6400 <i>GWhr per year</i>
b.	The actual Annual Energy Output is	27.727 <i>GWhr per year</i>
c.	Capacity Utilization Factor (CUF) [c = b/a]	22.61%

Table 2 Cost Analysis of Research Site

<i>Parameters</i>	<i>Generation per year (MWhr per year)</i>	<i>Capital Expenditure (INR)</i>	<i>Total Generation in 25 years @1% degradation</i>	<i>Cost of per unit generation (INR)</i>
Existing Wind farm	14003.955	696,000,000	311137968.5	2.25
Proposed Wind farm	27716.640	1050,000,000	618394646.1	1.70

- IPPs (Independent Power Producers) and FDI (Foreign Direct Investment) needs to be encouraged by the government;
- Old project owners needs to be given freedom to choose alternate option for sale of power i.e. REC Mechanism, third party sale etc.

Grid Augmentation

All the WTGs in Muppandal are connected at 11/33/66 KV rural feeder level and most of the WTGs available in the market today are designed as per 33 KV/ 220 KV level as it minimizes losses due to step-up and transmission. For new projects, TRANSCO/TANGEDCO needs to allow interconnection at higher (110/220) KV levels. Considering the congestion of grid lines at Muppandal Pass, it would be advisable to allow interconnectivity at 220 KV level.

NIWE Certification

The wind regime at Muppandal Pass is suitable for Class IIIA / IIA turbines and in certain cases even Class IB turbines can be used. But most of the current WTGs sold in India are suitable for low wind sites i.e. class IIIA/IIIB sites and manufacturers like Suzlon who have higher class turbines (class I/II) in their portfolio have stopped manufacturing such turbines due to either lack of demand or lapsing of their NIWE (National Institute of wind energy, formerly CWET) certifications. NIWE needs to allow fast-track revival of such types of certificates for manufacturing of higher class turbines of limited numbers for these repowering Projects.

The additional decommissioning cost for old turbines (such as transport charges) needs to be assessed.

Conclusion

The interdependence of economic growth and energy consumption cannot be denied, so access to a stable energy supply is important to the political world and a technical and monetary challenge for both developed and developing countries, because prolonged interferences can generate serious economic and basic functionality difficulties for most societies. Renewable energy sources are evenly distributed around the globe as compared to fossils and generally less traded. Conventional sources of energy are unsustainable from economic and environmental aspects whereas renewable sources like wind and solar energy are limitless and create almost no pollution.

Renewable sources also reduce energy imports and contribute to the diversification of energy supply options, reducing an economy's vulnerability to price volatility and at the same time representing opportunities to enhance energy security across the globe. They can contribute towards increasing the reliability of energy services in areas that often suffer from insufficient grid access. A diverse portfolio of energy sources together with good management and system design can help to enhance energy security. Also, renewable energy technologies enable countries to utilize renewable energy sources to meet their domestic demand and even have long-term export potential.

Renewable energy technologies could reduce CO₂ emissions by replacing fossil fuels in the power generation industry and transportation sector. Enhancing energy efficiency regardless of type is also crucial for climate change mitigation and reduction of environmental and health impacts.

This article focuses on wind energy technology and the way to optimize the efficiency of old wind farms through repowering method. It presented the repowering aspects both financial and electrical of Jamgodrani wind farm. The research work pointed out a number of advantages in this analysis which shows that the Repowering of considered farm could increase its annual energy production by 10% (from 12.26% to 22.61%) while using only 7 turbines instead of 58 turbines presently in used which also reduces the environmental impact. Furthermore the financing of repowering and government subsidies could also reduce the cost burden of repowering. Overall it can be said that these are strong evidences that repowering is a profitable investment in electrical, economic and environmental aspects.

Future Scope of the Research Work

The field of wind energy has a tremendous scope for innovation and large economic opportunities. The advanced wind modeling software such as windPRO, WindFarmer, Windographer and WAsP can be used for micro-siting, wind resource assessment, predicting annual energy production and wake analysis for obtaining better results for repowering at higher heights and as well as at complex terrain. These advanced software consist of several modules which enables to create wind statistics, perform simple or complex energy calculations and generate resource maps.

PREFACE

The *Encyclopedia of Renewable and Sustainable Materials* is a novel initiative, launched to cater for researchers, industrial practitioners and environmental conservationists to bring to the fore the issues of renewability, regeneration, recyclability and sustainability of natural material resources for the greater good of the environment, society and renewable resources. With these objectives the project was constituted of 11 sections, led by one Section Editor each. There are about 4,000 printed pages, accommodated in five volumes ranging from 600 to 1000 pages each.

This encyclopedia is the primary reference source for researchers at different levels and stages in their career in academia and industry and those with an interest in environmental protection and sustainability, including re-use and recycling of natural and synthetic materials and regeneration of natural materials. The work encompasses the knowledge and understanding of many experts into a single, comprehensive work of about 370 articles comprising a combination of review articles, case studies and research findings resulting from research and development activities in both industrial and academic domains. The encyclopedia, focuses on how some of these topics bring advantages for a broad range of technologies and environmental protectionists. These include harnessing existing materials both natural and synthetic, their re-usability and regeneration possibilities for the greater good of society and the environment. The aspects of feasibility, conservational objectives and practicability of implementation have been addressed through a number of relevant articles.

As Editors in Chief of this five-volume comprehensive publication, a truly collaborative work, we are greatly indebted to the 11 Section Editors who are internationally renowned experts in their fields, for guiding and selecting the topics for their respective sections which constitute the five volumes, commissioning authors and reviewing the contents so meticulously. Their true dedication to the scientific community and society is reflected in the time and energy they have given to this project. My sincerest thanks are due to all the authors – researchers, environmental protectionists and practitioners who have contributed extensive coverage of literature review as well as recent works of research to this substantial five volume encyclopedia. The excellent insight and specialist knowledge in their respective fields is reflected in the high quality content of this unique work.

Both of us and all the section editors are greatly appreciative of all the hard work undertaken by all concerned to turn this concept of the *Encyclopedia of Renewable and Sustainable Materials* into a publishable work. Our special thanks go to Ruth Rhodes and Michael Nicholls, the Project Manager, along with Kshitija Iyer and the rest of the team at Elsevier who served successively to keep the project on track through friendly nudges in order to ensure timely completion. We are also hugely grateful to other colleagues at Elsevier production unit for the coordination of the proofs.

The extensive research treatment of core ethos of renewability, recyclability and regeneration, supplemented by applied case studies has drawn together many areas of research and we sincerely hope that this work will prove to be of great help to both the young and experienced members of the international research community, academics and industrial practitioners associated with sensible utilization of natural and synthetic materials for many years to come.

Saleem Hashmi and Imtiaz Ahmed Choudhury
Editors in Chief – *Encyclopedia of Renewable and Sustainable Materials*

Renewable Materials in Building, Construction, and Architecture

Analysis of the Thermal Performance and Comfort Conditions of Vernacular Rammed Earth Architecture From Southern Portugal <i>Jorge Fernandes, Sandra M Silva, Ricardo Mateus, and Elisabete R Teixeira</i>	1
Architecture Follows the Sun: Climatically Responsive Architecture and Process of Design <i>Arvind Krishan</i>	11
Bamboo Structural Technology <i>Sanjay Prakash and Divya Chand</i>	35
Conservation of Material, Technology and Practice in Heritage Structure and its Relevance in Today's Context <i>Apoorva Dandge and Sheeba Valsson</i>	39
Constructing a PV-Integrated Permanent Bamboo Building – An Experience <i>Madhumita Roy and Saroj Mandal</i>	50
Energy Efficiency and Thermal Comfort in Heritage Buildings <i>Anjali K Sharma</i>	58
Environmental Life Cycle Analysis of Earthen Building Materials <i>Ricardo Mateus, Jorge Fernandes, and Elisabete R Teixeira</i>	63
Evaluating the Sustainability Performance of Building Systems and Technologies for Mainstreaming Sustainable Social Housing in India <i>Rajat Gupta, Sanjoli Tuteja, Sanjay Seth, Megha Behal, Zeenat Niazi, Pratibha Caleb, Jesús S Villanueva, and Ayushman Banerjee</i>	69
Evaluation of Sustainability Indicators of Buildings <i>Anjali K Sharma</i>	87
Expediting Faster Housing Supply in India Using Straw Bale as Prefab Building Material <i>Monika S Gupta, Uttam K Roy, and Madhumita Roy</i>	92
Improving Building Technologies With a Sustainable Strategy <i>Jayashree Deshpande</i>	102
Improving Energy Efficiency in Buildings Through Responsible Design: Optimizing Use and Careful Selection of Building Materials <i>Madhumita Roy and Bharati Mohapatra</i>	110
Insulation Materials for the Building Sector: A Review and Comparative Analysis <i>Marco Casini</i>	121
LCCA and Environmental Impact of Buildings <i>Hina Zia</i>	133
Leadership in Energy and Environmental Design Rating System: A Global Tool to Assess Sustainability in Buildings, Communities and Cities <i>Mili Majumdar</i>	144

Life Cycle Assessment Methods and Procedures and Their Role in Measuring the Sustainability Component of a Construction Technology <i>Ujwala Chakradeo and Tarika Mohite Dagadkar</i>	158
Material Culture and Sustainability: Traditional Versus Modern in a Case of Northeast India <i>Mainak Ghosh and Farha Shermin</i>	167
Retrofitting of Buildings/Built Environment – A Sustainable Development Model <i>Anjan Mitra and Saptarshi Mitra</i>	179
Roof Gardens to Vertical Farming <i>Abraham George</i>	199
Study of Junctions With Bamboo: An Attempt Towards Their Classification <i>Rajarshi Ray and Parthasarathi Mukhopadhyay</i>	205
Sustainability and Green Building Rating Systems: A Critical Analysis to Advance Sustainable Performance <i>Laura Florez</i>	211
Sustainability of Advanced Materials in Construction <i>Marco Casini</i>	221
Sustainable Architecture, Alternative Concepts and Waste Reduction <i>Abraham George</i>	232
Thermal Adaptation and Sustainable Housing in Cold Climates <i>E Rajasekar, Ghanshyam Thakur, and Belay Zeleke</i>	244
Traditional Crafts as Materials in Placemaking: Application and Sustainability in Aesthetic Transformation of Geometry of Urban Public Spaces <i>Jayati Mukherjee and Mainak Ghosh</i>	259
Understanding High Performance Buildings: The Link Between Occupant Knowledge of Passive Design Systems, Corresponding Behaviors, Occupant Comfort and Environmental Satisfaction <i>Mili Majumdar</i>	292
Use of Lime Mortar and Post-Occupancy Thermal Performance Analysis of Buildings <i>Mona Doctor-Pingel and Vishnu Vardhan</i>	302
Use of Steel as a Sustainable Concept <i>Anjan Mitra</i>	315
Using Construction and Demolition Waste as Construction Materials for a New Building <i>Madhumita Roy</i>	330

Sustainable Materials and Technologies

Advanced Polymeric Coatings and Their Applications: Green Tribology <i>Pixiang Lan, Emerson E Nunez, and Andreas A Polycarpou</i>	345
Application of Life Cycle Assessment for Sustainability Evaluation of Transportation Fuels <i>Najmul Hoque, Ilyas Mazhar, and Wahidul Biswas</i>	359
Biochar Production From Biomass Waste-Derived Material <i>Asfaw G Daful and Meegalla R Chandraratne</i>	370
Biocompatible Thermoplastic Composite Blended With HAp and CS for 3D Printing <i>Nishant Ranjan, Rupinder Singh, and Inderpreet S Ahuja</i>	379
Characterization and Interface of Natural and Synthetic Hybrid Composites <i>A Atiqah, M Chandrasekar, T Senthil Muthu Kumar, K Senthilkumar, and Mohamed NM Ansari</i>	389

Characterization and Phase Diagram of the Tetragonal Tungsten Bronze Type Ferroelectric Compounds $Pb_{2(1-x)}Gd_xK_{1+x}Nb_5O_{15}$ for Energy Storage Applications <i>Yaovi Gagou, Yassine Amira, Nadir Aliouane, Aimad Belboukhari, Billal Allouche, Abderrahim Menny, Jean-Luc Dellis, Daoud Mezzane, Mimoun El Marssi, Christian Masquelier, Matthieu Courty, Mohamed Elaatmani, and Pierre Saint-Grégoire</i>	401
Conversion of Renewable and Food Wastes Into Useful Products with Environmental Perspectives <i>Mohammad R Kasaai</i>	413
Energy Storage Device From Polymeric Waste Based Nano-Composite by 3D Printing <i>Rupinder Singh and Ranvijay Kumar</i>	425
Green and Healthy Alkaline Materials <i>Souad Al-Bat'hi</i>	433
Heat Affected Zone Morphology of TIG Torch Welded HSLA Steel in Presence of Ti and V Microalloying Elements <i>Moh HA Musa, Md Abdul Maleque, and Mohammad Y Ali</i>	439
Historical Development of Hybrid Materials <i>Mohd RBM Rejab, Mohammad HBM Hamdan, Ma Quanjin, Januar P Siregar, Dandi Bachtiar, and Yusrizal Muchlis</i>	445
Interface Study of $SiC_p/6061Al$ Composite <i>Adetayo A Adebisi, Md Abdul Maleque, and Kamilu A Bello</i>	456
Life Cycle Assessment in Buildings: An Overview of Methodological Approach <i>Grace KC Ding</i>	462
Lifecycle Assessment of Building Materials – A Cradle-to-Gate Approach <i>Grace KC Ding</i>	476
Life Cycle Cost Analysis for Green Buildings <i>IMCS Illankoon, Vivian WY Tam, and Khoa N Le</i>	489
Nickel Chromium Based Partial Denture Preparation: Conventional vs Additive Manufacturing Techniques <i>Gurpartap Singh, Rupinder Singh, and Sarbjit Singh</i>	500
Particulate Composite Protective Coating Using Conventional Melting Approach <i>Md Abdul Maleque, Nazrin Idris, Mohammad M Rahman, and Mohammad S Hossain</i>	510
Preparation of Partial Denture With Nano HAp-PLA Composite Under Cryogenic Grinding Environment Using 3D Printing <i>Nishant Ranjan, Rupinder Singh, and Inderpreet S Ahuja</i>	517
Processing of Ceramic Composite Coating via TIG Torch Welding Technique <i>Kamilu A Bello, Md Abdul Maleque, and Adetayo A Adebisi</i>	523
Removal of Chromium With CNT Coated Activated Carbon for Waste Water Treatment <i>Nassereldeen A Kabbashi, Abdurahman H Nour, Ma'an Al-Khatib, and Md Abdul Maleque</i>	536
Residual Stress Analysis for Sustainable Structural Integrity Assessment of an Engineering Component <i>Mohammad S Hossain and Md Abdul Maleque</i>	548
Solid Polymer Waste Materials for Repairing of Heritage Composite Structure: An Additive Manufacturing Approach <i>Rupinder Singh and Ranvijay Kumar</i>	557
Statistical Analysis of Energy Absorption in Aluminum Foam Sandwich Under Impact Testing Using the Taguchi Design <i>Muataz HF Al Hazza, Amalina Endut, Erry YT Adesta, Nur AB Ibrahim, and Mohammad Y Ali</i>	563

Structural, Thermal, Mechanical and Rheological Properties of Polylactic Acid/Epoxidized Soybean Oil/Organoclay Blends <i>Fathilah B Ali, Hazleen Anuar, and Jamarosliza Jamaluddin</i>	569
Sustainable Construction Achieved Through Life Cycle Assessment: Methodology, Limitations and the Way Forward <i>Karoline Figueiredo, Ahmed WA Hammad, and Assed Haddad</i>	576
Synthesis of High Grade Activated Carbons From Waste Biomass <i>Animesh Pal, Kutub Uddin, Kyaw Thu, Bidyut B Saha, Hyun-Sig Kil, Seong-Ho Yoon, and Jin Miyawaki</i>	584
Synthesis, Characterization and Applications of Nano-Structured Sol-Gel Coatings <i>Shimaa M Ali</i>	596
Tailor-Made Bioplastics for Environmentally Friendly Food Packaging: A Methodological Approach to a Challenging Problem <i>Clizia Aversa, Michela Puopolo, and Massimiliano Barletta</i>	605
Thermophysical and Adsorption Characteristics of Waste Biomass-Derived Activated Carbons <i>Animesh Pal, Kutub Uddin, Kyaw Thu, Bidyut B Saha, Hyun-Sig Kil, Seong-Ho Yoon, and Jin Miyawaki</i>	617
TIG Torch Melting as Surface Engineering Technology <i>Muhammad Azwan, Md Abdul Maleque, and Mohammad M Rahman</i>	629
Tribological Interactions of Advanced Polymeric Coatings <i>Reza Gheisari, Pixiang Lan, and Andreas A Polycarpou</i>	638
Waste Conversion Into Sustainable and Reinforcing Fillers for Rubber Composites <i>Xianjie Ren and Katrina Cornish</i>	648
Waste Printed Circuit Board (WPCB) Recovery Technology: Disassembly and Desoldering Approach <i>Muammer Kaya</i>	658
Waste Printed Circuit Board (WPCB) Recycling: Conventional and Emerging Technology Approach <i>Muammer Kaya</i>	677

Analysis of the Thermal Performance and Comfort Conditions of Vernacular Rammed Earth Architecture From Southern Portugal

Jorge Fernandes, Sandra M Silva, Ricardo Mateus, and Elisabete R Teixeira, University of Minho, Guimarães, Portugal

Introduction

From the beginning, humans had to look for shelters to protect themselves from other animals and the climatic elements. But it was in the Neolithic, when humans moved from a nomadic to a sedentary life, that they decided to build permanent shelters. These shelters evolved over thousands of years and generations, across the world, and diverse vernacular techniques and forms have been developed and improved to better respond to climate constraints and to provide the best comfort conditions possible.

To attain thermal comfort conditions vernacular buildings were built using low-tech passive strategies that take advantage of available endogenous resources and other criteria such as sun exposure, geometry, form, and materials, among others (Coch, 1998; Singh *et al.*, 2011; Fernandes *et al.*, 2015a,b). With the industrialization of the building sector, the vernacular knowledge was often forgotten in building design and its use declined. Moreover, nowadays, buildings too often rely on heating, ventilation, and air conditioning (HVAC) systems to ensure indoor thermal comfort conditions (Fernandes *et al.*, 2015a,b). Thus, the relevance of vernacular features is still valid today in the scope of sustainability, being the basis of what is now defined as sustainable building design (Cardinale *et al.*, 2013).

Environmental awareness is increasing and underlining the problems related to energy efficiency and environmental impacts in buildings. The building sector is one of the largest energy and natural resources consuming sectors, being responsible for a third of global total CO₂ emissions and primary energy use (Ürge-Vorsatz *et al.*, 2015). Therefore, new high-performance building concepts have been defined, such as the “nearly zero-energy buildings” (nZEB). An nZEB is a building with a very high energy performance (due to an improved envelope and use of very efficient HVAC systems) and where the very low energy demand must be covered by energy from renewable energy sources.

The awareness of vernacular architecture regarding passive and low energy architecture is increasing, since it is intrinsically related to the local climate, uses passive, low-tech techniques, and is not dependent on nonrenewable energy sources (Kimura, 1994; Singh *et al.*, 2011; Fernandes *et al.*, 2013), which makes these strategies suitable and valuable to achieve the nZEB level in different climate contexts.

Several studies have shown that vernacular buildings have a good thermal performance, allowing achieving acceptable thermal comfort levels during most of the year by passive means only, reducing the energy demand for heating and cooling (Martín *et al.*, 2010; Singh *et al.*, 2010; Priya *et al.*, 2012; Cardinale *et al.*, 2013; Fernandes *et al.*, 2015a,b).

In Portugal, there are some studies focusing on the passive strategies used in the vernacular building, but there is a lack of results showing the influence of these strategies on the thermal performance of vernacular buildings, namely of rammed earth buildings.

Portugal is a relatively small country, but it is a territory full of contrasts. Even though the variation in climatic factors is rather small, they are sufficient to justify significant variations in air temperature and rainfall, as can be seen in Fig. 1, which shows the differences in mean air temperature for mainland Portugal during winter and summer.

As Fig. 1 shows, the northern part of the country has cold winter and dry and mild summers, while in the southern part, the winters are mild, and summers are warm and dry. As a response to these differences, Portuguese vernacular architecture developed specific and different strategies in both regions. In the north, these strategies are more oriented to increase heat gains and reduce heat losses during winter, while in the south they are more focused on passive cooling during summer. A more detailed explanation about the characteristics of these vernacular strategies can be seen in the following sections.

As vernacular architecture has shown, a building solution/strategy does not fit all contexts. The diversity of vernacular construction systems that exist in Portugal leads to the necessity of understanding the actual performance of these buildings. In this study, the main goal was to measure the hygrothermal parameters that characterize the indoor thermal environment and that affect the heat exchanges in vernacular rammed earth buildings from Southern Portugal.

Vernacular Architecture in Inland Southern Portugal

Vernacular architecture from the southern part of Portugal has developed specific mitigation strategies to suit the local climatic conditions mentioned above. As seen in Fig. 1, summer is the most demanding season in the region due to the intense heat. Therefore, in general, the strategies present in this type of building are more oriented for passive cooling (Fernandes *et al.*, 2015a,b). From these, the more common and frequent are (Fig. 2(a–h)) as follows:

- (1) To minimize the size and number of windows exposed to the outdoor environment to reduce solar gains. Also frequent is taking advantage of the wall's thickness to recess the window in the facade, allowing depth to act as a shading system (Fig. 2(a)).
- (2) The use of heavy weight building elements, with a high thermal inertia, as rammed earth walls and domes, to dampen the flow of the thermal wave and to increase the height and thermal stratification, respectively (Fig. 2(b)).

Fig. 1 (left) Winter and (right) summer mean air temperature maps for mainland Portugal. Adapted from Fernandes, J., Pimenta, C., Mateus, R., Silva, S.M., Bragança, L., 2015b. Contribution of Portuguese vernacular building strategies to indoor thermal comfort and occupants' perception. Buildings 5, 1242–1264.

- (3) The use of white-washed surfaces, to reflect the incident solar radiation (Fig. 2(a)).
- (4) Ventilation openings integrated into windows and/or walls, to foster air circulation and night cooling to remove diurnal thermal loads (Fig. 2(c–d)). In some cases, these ventilation openings have gridded shutters, like the *mashrabiya*. These techniques allow simultaneously ventilation and shading from intense light and radiation without compromising privacy and security.
- (5) The use of patios (courtyards), usually containing vegetation and/or water, useful to generate a cool microclimate through evapotranspiration and water evaporation, respectively (Fig. 2(e)).
- (6) Vegetation is also frequently used as a shading system (Fig. 2(f)).
- (7) In an urban context, the use of a compact and irregular layout with narrow streets is also frequent, allowing for reducing the surface area exposed to the sun's rays and enabling buildings to provide shade for one another, thereby reducing solar gains by the building envelope (Fig. 2(g–h)).

These strategies are often combined to maximize their effectiveness to achieve a comfortable thermal environment, as shown in other studies (Fernandes *et al.*, 2015a,b). From these strategies, there is one that stands out for being the building element that characterizes Portuguese southern vernacular architecture. The heavy walls made of rammed earth are the most widespread vernacular construction technique in the southern, and mainly in the Alentejo region (the major area of all the southern part of Portugal). The heavy mass and the good heat storage capacity of rammed earth walls allow them to react appropriately to the hot summer of Alentejo, dampening the outdoor thermal wave and keeping indoor temperature and relative humidity stable (Martín *et al.*, 2010; Fernandes *et al.*, 2015a,b). The use of rammed earth in the region is ancient and there are several possible factors to explain it, such as the flat terrain, dry climate, the abundance of clayey material, and cultural influences from Romans and Moors.

The continued use for centuries of these strategies indicates the effectiveness in mitigating the effects of the climate and, therefore, the quantitative study is useful to discuss their potential nowadays in scope of energy efficiency and sustainability.

Fig. 2 (a) Small window recessed in a white-washed façade; (b) vaulted ceiling; (c) ventilation shutter integrated into window frame; (d) ventilation openings integrated into wall; (e) a patio containing vegetation and fountain; (f) vegetation shading the façade; (g–h) compact layout with shaded narrow streets.

Case Study Description

The case study is a rammed earth building located in the center of an old village, in the municipality of Moura, southern Portugal (Fig. 1). The Safara territory has an ancient occupation, with some archeological remains dating back to the 2nd Iron Age. The Romans (3rd century BCE to 5th century CE) and the Arabs (8th to 13th century CE) had a long dominion on this territory, having been integrated into the kingdom of Portugal in the 13th century. The origin of the village name has been attributed to the Arabs and means extensive plain without trees, but also adjectives such as *desert*, *arid*, and *harsh*.

This region is characterized by having a Mediterranean climate (subtype Csa), with a hot and dry summer (AEMET and IM, 2011). Summer is the most demanding season in this area, with an average maximum air temperature between 32 and 35°C, but sometimes the maximum temperatures can reach 40–45°C. July and August are the hottest months (AEMET and IM, 2011). The number of days in the year with a maximum temperature above or equal to 25°C is greater than 110 days in a large part of the southern area (AEMET and IM, 2011). In summer, the inland has more than 80 days with a maximum temperature above or equal to 25°C (AEMET and IM, 2011). In terms of precipitation is one of the Portuguese regions with less rainfall (the average value is less than 500 mm), July being the driest month (less than 5 mm) (AEMET and IM, 2011).

To cope with this climate, vernacular buildings from this region have several strategies to minimize heat gains and to promote passive cooling, such as small and few windows and doors, the use of high thermal inertia construction solutions, the use of patios (courtyards), the use of light colors on the envelope to reflect solar radiation, and ventilation openings. Regarding the latter, these are usually integrated into the upper part of windows and doors to promote air circulation, and are particularly useful for night-time cooling without compromising the safety of the building (Fernandes *et al.*, 2015a,b).

The village is strategically implanted next to the confluence between a river and two streams. It is located in a plain area of fertile agricultural land (abundant in cereals and olive trees). However, it is implanted in the transition area to the rugged terrain of streams' valleys and on the less fertile soil (lithosols), in border limit of the fertile land (Fig. 3(a)). Additionally, the characteristics of the surrounding soils show that they are rich in clay (luvisols and vertisols) (Fig. 3(b)), and at a lithological level there is presence of limestone and calcareous formations (Fig. 3(c)). These features were favorable factors in this site for using earth as a building material – The clayey soils for rammed earth, tiles, and bricks; and the limestone to produce lime for plasters, whitewash, etc. For example, the former military walls of Safara were built in rammed earth.

The village's urban layout is compact with a mix of narrow and wide streets, composed mostly of single-story buildings. Most of the buildings have a private courtyard, with vegetation that acts as thermal regulator, as explained in previous sections. The irregular and compact urban layout of narrow streets, with almost no streets and facades facing south, allows for reducing heat gains by the building envelope.

The case study building has an approximate gross floor area of 200 m² divided into two floors; however, the upper floor is just a small attic (originally a granary), usually not occupied. The living areas and the bedrooms are located in the southeast part of the ground floor, and the kitchen and the bathroom are located in the northern part (Fig. 4).

The envelope of the case study building consists of white-washed heavy weight external walls made of rammed earth with an average thickness of 60 cm (as the heavy thermal inertia delays the effect of outdoor temperature variation and stabilizes indoor temperature), pitched roof with ceramic tiles and reeds on timber structure (a small insulation layer of sprayed polyurethane foam was added a few years ago), wooden doors and wooden framed single glazed windows (Fig. 5). Indoor partition walls are in rammed earth and several of the indoor spaces are vaulted and the floor is paved with *baldosa* – a sun-dried clay tile. The building does not have an air-conditioning system and the only heating "system" is a wood-burning stove (in the living room) and the sporadic use of electric fan heaters (in the other rooms).

Materials and Methods for the Evaluation of Thermal Comfort Conditions

The purpose of the study was to assess indoor thermal performance and comfort conditions of a rammed earth building, measuring hygrothermal parameters that characterize indoor thermal environment and affect the body/environment heat exchange (air temperature, relative humidity, mean radiant temperature, and air velocity). In this study, to assess indoor thermal performance, the in situ measurements were divided into short- and long-term monitoring.

The first were carried out at least one time (usually one day) per season and were performed with the purpose of quantitatively assessing the thermal conditions within a specific room using a thermal micro-climate station (model Delta OHM 32.1) equipped with the probes required, namely, globe temperature probe Ø150 mm (range from –10°C to 100°C); two-sensor probes for measuring natural wet bulb temperature and dry bulb temperature (range from 4°C to 80°C); combined temperature and relative humidity probe (range from –10°C to 80°C and 5–98%RH); and omnidirectional hot-wire probe for wind speed measurement (range from 0 to 5 m/s). This data is used in the analysis of the thermal comfort conditions to determine the operative temperature, namely in the adaptive model of comfort, as explained below. Simultaneously, occupants were surveyed to evaluate their satisfaction with the indoor thermal environment, according to ASHRAE survey and thermal sensation scale (ASHRAE, 2004). The results of both procedures were then compared to conclude if converged or diverged.

Long-term monitoring had the aim of understanding fluctuations of air temperature and relative humidity, indoors and outdoors, throughout the various seasons. Therefore, combined temperature and humidity sensors were installed outdoors and indoors (in the most relevant rooms) for the assessment of thermal performance. The equipment used was composed by a thermohygrometer with datalogger (model Klimalogg Pro, TFA 30.3039.IT) (temperature range between 0 and 50°C with accuracy of ±1°C; humidity range from 1% to 99% and accuracy of ±3%), and a set of wireless thermohygrometer transmitters (model 30.3180.IT) connected to the datalogger (the transmitters have the same accuracy values; temperature range from –39.6°C and +59.9°C and relative humidity range from 1% to 99%).

The air temperature and relative humidity measurements were carried out for periods of at least 25 days in each season and with the different thermohygrometer sensors recording data at 30-min intervals. Results on indoor environmental climate parameters were correlated with the outdoor parameters. During these measurements, occupants filled an occupancy schedule where

they documented how they used the building (occupation periods, opening windows pattern, for example). These occupancy records were useful to understand, for example, sudden changes in air temperature and relative humidity profiles. The weather data used in the study was collected from the nearest weather station (approximately 5 km). All the measurements were carried out according to standards ISO7726 (2002), ISO7730 (2005), and ASHRAE 55 (2004).

Contribution of Portuguese vernacular building strategies to indoor thermal comfort and occupants' perception. *Buildings* 5, 1242–1264.

Fig. 5 External view (left), living room (right), with the micro-climate station measuring.

In the analysis of thermal comfort conditions, the relation between indoor comfort temperature and outdoor temperature was evaluated using an adaptive model of comfort, since this is the most adequate model for naturally conditioned areas. To be more representative of the Portuguese reality, the chosen model was the Portuguese adaptive model of thermal comfort (Matias, 2010) developed in the Portuguese National Laboratory of Civil Engineering (LNEC), which is an adaptation to the Portuguese context of the adaptive comfort model of ASHRAE 55 (2004) and EN15251 (2007). The Portuguese model takes into consideration the Portuguese climate (temperate climate Type C according to Köppen-Geiger Climate Classification), typical ways of living and operating buildings. It also considers that occupants may tolerate broader temperature ranges than those usually mentioned in standards and that outdoor temperature highly influences occupants' thermal sensation. A more detailed explanation of the model can be seen in Matias (2010) and Fernandes *et al.* (2015a,b).

The operative temperature was calculated based on the results obtained in the measurements from the Thermal Micro-Climate Station. With the operative temperature (Θ_o) and the outdoor running mean temperature (Θ_{rm}) it is possible to represent in the adaptive chart the point that characterizes the thermal environment condition in the moment of measurement.

Results and Discussion

The analysis of the thermal performance focused on the two most demanding seasons in terms of thermal comfort in the Portuguese context, namely winter and summer.

Fig. 6 Thermal performance during summer. (a) Indoor and outdoor air temperature profiles; (b) indoor and outdoor relative humidity profiles. Adapted from Fernandes, J., Pimenta, C., Mateus, R., Silva, S.M., Bragança, L., 2015b. Contribution of Portuguese vernacular building strategies to indoor thermal comfort and occupants' perception. Buildings 5, 1242–1264.

Summer Monitoring

The summer monitoring was carried out from August 9 to September 13, 2014, and the results are presented in Fig. 6. It is possible to verify that during this period the outdoor mean air temperature was of about 26°C. During the day, the maximum air temperature was often higher than 35°C, reaching, in some days, nearly 40°C. The minimum air temperature was usually around 20°C. Although the daily outdoor temperature variation is high, the indoor temperature remained very stable during the monitoring period, with temperature values around 25°C (Fig. 6(a)). Due to its location near the roof, the attic was the room that recorded the highest temperature (27°C), while outdoor peak temperature was around 40°C. The indoor temperature profile shows that the high thermal inertia of the building envelope (e.g., thick rammed earth walls and vaulted ceilings) provides a high capacity to delay the effect of outdoor temperature variation and to stabilize indoor temperature.

The relative humidity profile also presented high outdoor day/night variation, presenting minimum values lower than 20% and maximum values of approximately 95% (Fig. 6(b)). On the other hand, indoor spaces had more stable relative humidity profiles varying between 40% and 60%. These differences were due to the hygroscopic inertia of the building systems, such as the rammed earth walls and the lime plaster, which have a moisture regulation capacity (Fernandes *et al.*, 2015a,b), by absorbing when it is excessive and releasing it when the air is dryer.

Fig. 7 shows the results of the thermal comfort conditions assessment in the living room. This room was chosen because it is where the occupants remain for longer periods during the day. The results showed that the thermal comfort conditions in the building are in the center of the limits defined for the Portuguese adaptive thermal comfort model, i.e., in a condition of thermal comfort. In the survey, one occupant answered as being “slightly cool” and two occupants answered as being “neutral” (comfortable), confirming the measurements.

Winter Monitoring

The winter monitoring was carried out from December 22, 2014 to February 7, 2015. From the results obtained it can be seen that outdoor air temperature presented several fluctuations, with maximum temperature rarely reaching 15°C during the day and minimum values frequently lower than 5°C during the night (Fig. 8). As observed for summer, the indoor temperature remained very stable with a temperature of approximately 15°C (Fig. 8(a)). The indoor rooms with higher temperature variation were the

Fig. 7 Thermal comfort temperature (operative temperature) in the living room during summer monitoring, based on the relation between the limits of the indoor operative temperature (Θ_o) for buildings without mechanical air-conditioning systems as a function of the exponentially weighted running mean of the outdoor temperature (Θ_{rm}). Adapted from Fernandes, J., Pimenta, C., Mateus, R., Silva, S.M., Bragança, L., 2015b. Contribution of Portuguese vernacular building strategies to indoor thermal comfort and occupants' perception. Buildings 5, 1242–1264.

Fig. 8 Performance during the winter. (a) Indoor and outdoor air temperature profile; (b) indoor and outdoor relative humidity profile.

ones where the occupants frequently use heating equipment (stove and electric heating fan), namely in the living room and kitchen. These were also the rooms with better comfort conditions, since the other rooms were not heated and although they had stable temperatures, they were below 18°C. Nevertheless, in **Fig. 8(a)** it is possible to see that when rooms are heated it is relatively easy to increase, and maintain, the indoor temperature above 18°C, and in some situations up to 25°C.

In winter, the relative humidity indoors was very stable, though with values above 60%, with the exception of the living room and alcove (around 50%) (**Fig. 8(b)**). The decrease observed in the living room could be associated with the use of heating (a wood-burning stove).

The evaluation of thermal comfort was carried out with the stove in operation. In the living room the comfort conditions are in the center of the comfort range (**Fig. 9**). However, the thermal sensation in the rooms without heating was

Fig. 9 Thermal comfort temperature (operative temperature) in the living room during winter monitoring when the heating system was on, based in the relation between the limits of the indoor operative temperature (Θ_o) as a function of the exponentially weighted running mean of the outdoor temperature (Θ_{rm}). Adapted from Fernandes, J., Pimenta, C., Mateus, R., Silva, S.M., Bragança, L., 2015b. Contribution of Portuguese vernacular building strategies to indoor thermal comfort and occupants' perception. Buildings 5, 1242–1264.

considerably below the thermal comfort range. Although the indoor temperature was considerably higher and more stable than outdoors, it was not possible to achieve thermal comfort conditions without heating. Nevertheless, it was verified that a simple heating system is sufficient to achieve thermal comfort conditions. The results from survey to the occupants supported the measurements, with three occupants answered as being “neutral” (comfortable) and one as being “slightly cool.”

Conclusions

The results of the thermal performance and comfort conditions assessment of the rammed earth building showed that is possible to achieve indoor thermal comfort just with passive means, confirming a strong relation of cause and consequence between vernacular architecture and the climatic context. The building had a high thermohygrometric performance during summer, the harshest season in this climatic zone, confirming the effectiveness of the passive cooling strategies. In winter, it was not possible to maintain thermal comfort conditions only with passive strategies. However, the thermal discomfort situations were overcome using a simple heating “system” (wood-burning stove).

It was noticed that the thermal inertia of the building, the solar exposure, the shading and natural ventilation devices, the adequate organization of the rooms taking into consideration solar orientation, and the action of occupants are significant aspects that have a positive influence in the indoor temperature and humidity profiles (e.g., promoting passive cooling by natural ventilation during the night and early morning, shutting doors and windows during the periods with incident radiation, etc.).

The results observed in this study allow concluding that with the use of a combined set of passive strategies, such as the passive cooling strategies during summer, it is possible to ensure thermal comfort conditions without using HVAC systems. The adoption of such strategies in buildings in this region can greatly contribute to reducing energy needs for cooling and therefore to reducing energy use and potential environmental impacts during the operation phase.

Considering the results and taking into consideration that the case study is an old building with building elements that are not optimized, it can be stated that the passive strategies used in vernacular architecture have high potential to be improved and adapted to new buildings, allowing thermal comfort while reducing energy demand.

Acknowledgments

The authors would like to acknowledge the support granted by the FEDER funds through the Competitiveness and Internationalization Operational Programme (POCI) and by national funds through FCT – Foundation for Science and Technology within the scope of the project with the reference POCI-01-0145-FEDER-029328, and of the PhD grant with the reference PD/BD/113641/2015, that were fundamental for the development of this study. The authors also wish to thank Mr. João Cordovil and Mrs. Isabel Gaivão for supporting this research work.

Good meaningful architecture emerges at the meeting point when art becomes science and science becomes art - Arvind Krishan

Part I: Unfolding Scenario

These are indeed exciting times to be alive; the moon has been “conquered,” and may pave the way for waves of immigrants from Planet Earth to colonize the moon. Mars is next. And to be part of building higher ever above the clouds, creating architecture that hitherto was not possible. While the Leaning Tower of Pisa (Italy) ([Fig. 1](#)) has been an attraction due to its tilt, perhaps because of a lack of understanding of foundation–soil behavior, now buildings are designed and built to lean as much as 18.5°, designed as “imperfect on purpose” ([Figs. 2 and 3](#)).

Emboldened by what technology can do in design and construction, architecture is reaching ever higher, becoming ever more curvaceous, twisting the logical into a questionable torso. “Smart” buildings, “smart” cities (whatever “smart” means) controlled by artificial intelligence will not only control the habitat and environment we live in, it seems to some that they may provide solutions to all ills of human habitation.

Algorithms produce architecture. They are increasingly becoming a critical part of the process of design. Architecture is formed/deformed by these complex algorithms that are fed into large capacity computing machines ([Fig. 4](#)).

The fundamental question: Is a holistic approach to sustainability based on ecology and the human condition part of any of these algorithms? Can an algorithm be generated based on amorphous issues of sustainable human habitat? ([Fig. 5](#)).

Importantly, a driving force behind change is how people are/will be using buildings of the future. Sensorial adaptive design, supported by technology, robotics, automation, new materials such as carbon nanotubes integrated with glass and new approaches to energy creation, such as solar glass use and storage, is shaping the buildings and cities of tomorrow.

In this era driven by technology, governed by rapid change, human habitat is changing in a manner that is no less than any cataclysm that humanity might have experienced.

Fig. 1 Leaning Tower of Pisa.

Fig. 2 Capital Gate Abu Dhabi.

Fig. 3 Cayan Tower Dubai.

Fig. 4 Elbphilharmonie in Hamburg.

Fig. 5 Sustainability.

The surge to urbanize, a policy adopted by the most populated parts of Planet Earth, India and China (2.74 billion people), which represent 40% of the 7.7 billion world population, as a solution to resolve conflicting issues that human habitat creates and faces, is translating habitat into questionable vertical expansion at unprecedented rate.

Steel and Glass Monoliths

Steel and glass monoliths are marching into every urban development on the planet.

"There's a creepy transformation taking over our cities," says architecture critic Justin Davidson in his TED Talk. From Houston, Texas to Guangzhou, China, shiny towers of concrete and steel covered with glass are cropping up like an invasive species (**Fig. 6**).

Having created megacities and urban spaces that are sterile and lack human scale these shiny steel and glass robots are increasingly creating inhuman living conditions and losing their value, other than creating expensive real estate for the rich and few who build these to live in or use (**Figs. 7 and 8**).

Fig. 6 Glass-steel & concrete towers underway: New York City.

Fig. 7 Tokyo.

Fig. 8 Hong Kong.

Principles of Design

In principle, fundamentals of planning and design remain: There is a structure, there is a building envelope, and there are services.

Le Corbusier's Brise Soleil

This evolved with a concrete frame structure wrapped by glass envelope bound together by modulating glass mullions in a proportion determined by “musical score.” This was in turn protected by concrete: Brise Soleil.

As contemporary buildings increasingly use glass as a significant cladding material, architectural designers are focusing more on functionality and the aesthetic qualities of glass. While transparency was, and remains, the dominant attribute for most projects in a glass envelope, many designs now use a more complete materiality palette encompassing reflectivity, color, thermal behavior, and surface materiality (Fig. 9).

Ubiquitous use of glass façades has turned these buildings into “glass boxes,” creating uninhabitable spaces both inside and outside. While the glass industry is evolving rapidly, it is still struggling to provide solutions to the basic parameters of architectural design: Daylight, heat transmission, and ventilation (Figs. 10–14).

A New Age “Brise Soleil” has Emerged

The design team sought to create an elegant, eye-catching tower by exploring interactions between simple form, light, and shadow.

The big questions are:

- (1) If control of heat transmittance is the real issue, why the glass envelope tower with a complex solid façade control over the glass envelope?

Fig. 9 High-Court Building Chandigarh (Le Corbusier).

Fig. 10 Capital Market Center – HOK.

Fig. 11 Green Land Center, Beijing.

Fig. 12 Smithsonian African American History National Museum.

Fig. 13 Al Bahr Tower UAE – Abu Dhabi.

Fig. 14 Al Bahr Towers: The real facade.

- (2) When heat transmittance can be controlled through a traditional/conventional solid envelope and fenestration pattern with controls that can be designed in response to solar geometry, in a simpler manner of construction and effectively, where is the need of Glass envelope?

Conclusion

Despite the enormous computing power of super computers, moving from glass towers of different shape, size, and color, realization finally dawned: A glass envelope is not an ideal solution. The glass envelope is now protected with different shapes and sizes, increasing their complexity, where planning and architecture of human habitat are begging for a true solution to generate a truly sustainable habitat. Once again, the past – Indigenous habitat – Is a repository of knowledge that offers the parameters for a solution.

Part II: Lessons From Indigenous Architecture

Indigenous architecture has evolved over a long period of time, in response to climatic conditions and socioeconomic parameters, which are largely amorphous. It is a repository of knowledge. A detailed study of two desert habitats, two deserts in India, the hot, dry desert of Jaisalmer (Rajasthan) and the cold, dry high altitude mountainous desert of Leh (Ladakh) was conducted by the author and his teams over period of 3 years (Krishan, 1996).

Jaisalmer and Leh are two cities unique as artifacts of human endeavor in extreme climates. They offer effective solutions to the extreme climates and the terrain.

Planning and design parameters derived from this study are presented here. These are critical for the process of planning and design of human habitat.

S. no.	Description	Jaisalmer: Hot dry desert of Rajasthan	Leh: Cold dry high altitude mountainous desert
1.0	Climate context	Climate of Jaisalmer is a typical hot dry desert. There is very little and unreliable rainfall (average annual precipitation < 200 mm). Two seasons are predominant: Summer and winter. In summer, the daytime temperature can reach up to 48°C (some peak conditions of 50°C have also been observed) and down to 25°C at night. Similarly in winter, temperature varies between 25°C and 5°C. The diurnal range of temperature is between 15°C and 20°C. Relative humidity in summer can be less than 10% in daytime. The sky is mostly clear and solar radiation is intense throughout the year. During the summer months the wind velocity is usually high and there are dust storms during May and June.	Climatic context of Leh is a very cold dry climate. There is very little rainfall; average annual precipitation is less than 115 mm. There is basically one season that is predominant in this area, that is, winter, which becomes very acute for a long period from November to March. The summer, that is, June and July, does offer a comparatively mild climate. The diurnal range of ambient temperatures in winter is about 16°C with the maximum mean recorded as –2.8°C (although a maximum of +3.2°C has also been recorded) and the minimum mean recorded as –14°C (although a minimum of –30°C has also been recorded). The summer diurnal range is above 15°C with the mean maximum recorded as +24.7°C (although +37°C has also been recorded). A diurnal range of 30°C has also been observed by us in the month of October. The relative humidity drops to an average of 30% in summer and rises to an average of 50% in winter.
2.0	Settlement patterns: Is the first level of control in response to climate.	Settlement pattern Jaisalmer  City is served by a triangular fortification and is characterized by narrow winding streets with densely built construction on both sides. It has reasonably large open spaces to serve the community. House planning and design is characterized by a courtyard-type house with an underground level. The house opens onto narrow streets through a hierarchy of spaces that becomes the interface between the street and the house. The entire city ranging from the small house to the Palace of the King is built in locally available light-yellow Jaisalmer's stone, which is basically a sandstone.	 Settlement pattern, Spituk Spituk is a very old monastic settlement dating back 700 years. It is located on a carefully chosen hillock in the valley reasonably close to the Indus River. The entire settlement has been developed on the southern steeply sloping face of the hillock to maximize exposure to the sun. The entire settlement is a very fine example of architectural planning and design. Where exposure to solar radiation is a primary determinant of the settlement pattern and its form. The design of all buildings is carefully controlled in their siting, orientation, plan-form, and total three-dimensional configuration, that is, height, volume, and form. To obtain maximum heat gain through solar exposure the hierarchy of spaces at the community level and individual house level have been so designed and provided such that maximum solar exposure is obtained.

3.0 Street layout

Street layout

Street section mutual shading

Fig. 3. (a) Typical street in Jaisalmer. (b) Mutual shading in a typical street section in Jaisalmer.

All major streets are oriented almost in the east/west direction at right angles to the direction of dust storms.

The famous Havelies with Jharokas and decorative facades are located on these streets. The streets are relatively narrow and winding. The height of the building compared with the width of the streets is large to create shaded environment for the pedestrians, and social activities on the streets.

Street photograph

Solar access Haliodone study

Fig. 14. (a)-(f) Solar access and solar penetration study.

Settlement of Spituk and other indigenous settlements do not have a street layout per se.

However, public circulation areas are clearly defined and a hierarchy of public/semiprivate/private is clearly defined.

Building mass orientation and spatial orientation are so organized that Solar access is maximized and privacy is respected.

A solar access study was done through Heliodon based photographic study. This clearly shows solar access on public and private, exterior spaces during two clear climate seasons, summer and winter, and at different times of the day.

4.0 Generic house

The generic house type in Jaisalmer is courtyard-type of house with unenclosed verandah around the courtyard, a rear enclosed room and an underground space used for storage and living. Variations of the courtyard house occur in the form of a simple single story house and elaborate havelies. A haveli belonging to the Vyas family has been studied in detail and monitored for thermal performance. The more elaborate havelies are normally two- to three- story structures with an underground living space.

Fig. 4 Typical haveli.

Generic house, Jaisalmer

Generic house, Leh

The generic house in Spituk as well as Old Leh is a compact two- to three-story house constructed in sun-dried mud blocks. The walls are made of dry stone masonry; they are very thick, tapering in thickness from ground floor to the top with average thickness being almost 1 m. The doors and window fenestrations are quite small. The houses provide hierarchy of spaces both enclosed and unenclosed where a good solar exposure is available. The buildings typically do not have any overhangs thus preventing any shading of the surfaces thereby maximizing the heat gain from direct solar radiation.

(Continued)

Chapter 11312 Continued

S. no.	Description	Jaisalmar: Hot dry desert of Rajasthan	Leh: Cold dry high altitude mountainous desert
5.0	Thermal performance	(i) Thermal performance of the haveli type is very good; in this type of building the maximum fluctuation of ground floor temperature was not more than 3.0°C while the outdoor temperature fluctuation was in the order of 15°C. The maximum indoor temperature was 8–9°C lower than the corresponding outdoor temperature. (ii) Ventilation fenestrations that are normally kept open throughout the day causes the building to be warmed up but they increased the air movement providing a greater sensible comfort. (iii) The combined effect of a greater time lag and a small decrement factor reduces the heat flux entering the building. (iv) The courtyard system ensures ventilation through the building even during the calm outdoor conditions. (v) Due to shadow patterns, the buildings receive minimum radiation from direct solar exposure. In the summer, this serves in reducing peak heat flux into.	Thermal performance of the typical Ladakhi houses is represented by the monitored thermal variation for both winter and late October condition (Fig. 13(a) and (b)). The winter monitoring is still in progress. The results are: (i) The thermal performance of the typical Ladakhi house is very good even against the very harsh winter climate. Whereas the ambient conditions fluctuate between minimum low of –20 to –5°C in winter and a minimum low temperature of 3–14.7°C in summer. The internal temperatures stay very stable and at best fluctuate between 12 and 15°C; although this is not in the comfort zone, stability in indoor temperature allows the temperature to be increased by a minimum auxiliary energy source, mostly in the kitchen which is, for this purpose, centrally located within the main living spaces. (ii) The thick mud walls provide a large thermal mass leading to a large time lag and small decrement factor, thereby effectively attenuating the external ambient conditions. (iii) Small window and door fenestrations provide the minimum aperture area for ingress of cold winds. (iv) Windows are typically splayed in the thick mud walls so as to provide minimal area of exposure on the outside and much larger area on the inside face of the wall. The mythical answer to this, given by the local people is that this keeps the evil spirits out of the dwellings. But there is a scientific reason behind this, that is, the splayed window allows a greater distribution of daylight inside the space, thereby minimizing the use of auxiliary energy for lighting spaces in daytime.
6.0	Thermal mass	Thick walls made of local stone effectively control thermal performance of the buildings. It keeps the daytime heat out.	Thick walls made of sun-dried mud blocks effectively control thermal performance of the buildings. It keeps the heat contained inside.
7.0	Conclusions	While indigenous habitats may be considered as old solutions, an in-depth study of thermal performance and analysis has proven they are highly sophisticated solutions to the complex issues of human habitat. Above study of two situations in extreme climates has lessons to teach us for modern planning and design issues. Settlement pattern in both extreme situations is unique response to solar access, wind/dust storm orientation, yet they provide for ample community level open space. Thermal mass–fenestration pattern ratios are very effective solutions. Natural ventilation can be achieved by fenestration location/shading and courtyards. Mutual shading at the entire settlement, street, and house levels is a very effective solution. For reference and detailed study see Krishan (1996).	

Part III: Climate Responsive Architecture: Scientific Process of Design

This section examines the process of design and presents generic approach to design.

Climate Responsive Architecture: The Tool and the Process

The process of architectural design is a complex exercise, involving interactive relationships between parameters of diverse nature and varying magnitude (Fig. 15). Yet, it is the prime generator of architecture as we see and experience.

Ecological process of design (Fig. 16)

Various ideas have dominated architectural thought from time to time. Yet, the fundamental issue of energy as an embodiment of sun, wind, and light – The ecological context – have not been a basic paradigm of design. Therefore, relationship between the built-form and ecology should become the driving force behind the process, based on a scientific methodology – Leading to climate responsive architecture.

The ideal climatic design: Successive modulation of ambient conditions so as to bring internal conditions within the comfort zone.

The relationship between built form and the environment should become the driving force behind this scientific process, based on a scientific methodology.

Available tools of analysis allow critical performance and evaluation of built and overall space network. It seems logical to develop a process, almost in the form of an algorithm, which will help find the optimal form/solution for a given set of requirements and constraints. Evidently based on a design hypothesis, it is possible to generate a set of solutions through this process/algorithm. From this set of solutions, the optimal solution can be arrived at. However, the reverse is not true.

Given a case (the design hypothesis) and a rule (the simulation model) one may obtain by deductive inference the unique possible result (the performance characteristics of the given hypothesis). If instead, one defines the required result (the performance characteristics)

Fig. 15 Process of design graphic representation.

Fig. 16 Ecological process of design graphic representation.

there does not exist a mode of inference by which, using a given rule (a specific algorithm), one may determine uniquely the case (the design solution).

The idea of climatically responsive design is to modulate the conditions such that they are always within or as close as possible to the comfort zone. The ambient conditions over a 24-h period are shown by the line A. For a majority of the time it is outside the comfort zone. Modulations introduced by the landscape, built form, envelope, materials, and other control measures bring the conditions within the comfort range throughout the 24-h cycle. This is the goal of climate responsive design.

However, unlike industrial manufacture, designing is not a linear process. Parameters are interrelated and interactive. Often, they need to be considered simultaneously and in a cyclical manner. Any process of design must, therefore, allow for this flexibility and dynamism. This process and the design tool are outlined in later sections. The basis of our attempt at climate responsive design involves considering climate as a parameter of design in every aspect of the building and built environment. Our first task is to put forth these various aspects in a logical sequence. In effect, we are dissecting the design into its constituent elements so that we can act upon each in turn. The sequence proceeds from macro level details to micro level details.

A qualitative study of these modulations, at each level, is an essential prerequisite to climatic design. What follows is just that. Each level is explained in terms of its climatic implication, the conceptual understanding thereof and its effect on the building design. The various levels together provide an extensive understanding of the interaction of the building and the microclimate. To enable the qualitative and quantitative analysis of landform the energy balance at the surface should be analyzed and the consequent effect of this be taken into account in the design process.

The information given in the preceding text is linked together into a comprehensive design aid by the *design tool*. On the face of it the tool is simply a color-coded ready reckoner. It helps in the formation of a conceptual design strategy. However, it is also linked to the qualitative and quantitative information. It, thereby, draws the reader into a more comprehensive and precise understanding of the requirements towards the design input.

The idea is to optimize the input of the designer and to direct the output of the aid into clear pointers for design. As a result the design-aid package seldom requires the designer to know much more than the basic climatic conditions and the latitude of the place. Only at an advanced stage of design (for instance, while determining glazing areas of sun spaces in a cold climate is more specific data required.

So how does the design tool work anyway? The tool displays the different levels and the broad options available within each. These options are color coded, with the colors indicating the zone they are appropriate for. (There is also a gradation of shades within the colors themselves. The darkest shade indicates the most desirable and the lightest shade indicates the least desirable option.) The color code is as follows:

- Yellow options for hot (overheated conditions)
- Blue options for cold (underheated conditions)
- Green options for moderate conditions

Climates that experience more than one extreme season have to be designed resolving the contradictions as far as possible.

A basic design strategy can be formulated by simply following the appropriate color path. At each level the reference for supporting qualitative and quantitative information is given. These can be referred to, to refine and translate the basic strategy into a design solution. Of course, this is simplifying the case. Each design would have a context of its own which needs to be acknowledged and accounted for. The tool evaluates landform variations but not all projects would have the scope for this. The cause of climatic design would, therefore, not be aided by a gospel like the Ten Commandments for each zone. Like the Commandments they would be seldom followed due to practical problems in doing so. What is needed is a guiding framework that allows each to find their optimum solution. The design tool does just that. The tool indicates the climatic imperative for the options. Therefore, not only are certain options highlighted but the climatic factor and its effect are also indicated. While the options have primary implications they may also have a secondary one, too. This also appears. As a result the user need not work blindly. Knowing the reason for the options being appropriate and the possible implications of each option, the designer need not just follow the color path downwards.

Design Matrix

The tool indicates the climatic imperative for the options. Therefore, not only are options highlighted but the climatic factor and its role is also indicated.

The web link below ties it to a very comprehensive analytical and design method.

(This process was developed independently by author and later integrated as part of EU research project by author along-with a team from UK, Greece, and India. It is available in the public domain) (Fig. 17).

Knowledge Based Expert System for Design Decisions

Note: The design matrix-climatic responsive process of design was developed by the author independently and published as part of the book *Climate Responsive Architecture* by Krishan *et al.* published by McGraw-Hill. It was later incorporated as part of an EU project as well.

Fig. 17 Design matrix and climatic responsive architecture.

Conclusion

Architectural designs (Part IV) generated by the ecological process of design have responded well to climate.

Part IV: Some Contemporary Solutions

Sustainability and architecture are synonymous terms. While sustainability physically and economically is to a large extent manifest in the habitat built form, it is the scientific temper that will lend a design methodology and process, in order to render architecture sustainable. To achieve this, an energy resource flow–ecological footprint model is suggested, which can help optimize input/output parameters and their relationship. Possible formulation of these parameters leading to a sustainability indicator is also suggested. This leads to a process of design and various actual projects in response to critical issues. Thus, suggesting a new language of architecture.

Preamble

Sustainability, a keyword and catchphrase used by professionals and politicians alike, is an issue that will determine decision making for the next millennium, and it has been an integral part of the life cycle since humankind took charge of its destiny. Although then, it did not have the high-profile definition that it has now. Human habitat and nature were synonymous – habitat of cold deserts of Ladakh (India), the hot deserts of Jaisalmer (India), the plains of Hyderabad (Sind) stand as testimony (Part 2). Yet, today with a technology that can put man on the moon, and clone sheep, we find ourselves on the verge of a global environmental catastrophe.

When the entire planet seems to be hurtling perhaps towards an unsustainable future: Architecture – the human habitat, which is the largest consumer of natural and manmade resources, in my considered opinion – offers a potent tool for moving towards a sustainable future. It more than ever calls for a new language of architecture.

Present Scenario: Urban Dilemma

Central to the issue of sustainability at the global scale is the human-habitat condition that now prevails in large and highly populated countries such as India and China, which together make up 40% of the total world population.

Urbanization in India has risen from 11.4% in 1940 to 28.52% in 1991, is currently 33.56%, and is planned to grow to 75%; this is a phenomenon that is changing the urban context at a very fast rate.

Indigenous cities of Indian civilization, which bear witness to human history of many a millennium – Mohenjodaro, Harrapa, Jaisalmer – are home to architecture of excellence. Yet, the indigenous city in the context of today is virtually overwhelmed by population explosion. Any of the modern developmental/infrastructural solutions prove counterproductive.

Emerging Scenario

A literal crisis situation in urban areas and an alarming depletion in natural resources in India prevail. The environmental conditions thus prevailing demand a radical shift in planning and design paradigm.

Fig. 18 Knowledge based Expert System for Design Decisions.

Fig. 19 Design Decision Matrix.

Energy Resource Flow–Ecological FootPrint Model

Human habitat, a physical manifestation of socioeconomic ecological context, is the major consumer and generator of energy and resource. The energy resource flow model presented below illustrates the input–output relationships.

While air, water, and land are the environmental major resource inputs; materials (embodied energy), fossil fuels (primary energy) are the major natural resource inputs. Outputs, that is, emissions, are the major source that modify the environmental context. This input-output intrinsic relationship determines the ecological footprint: The community, city or the region/country – the ultimate determinant of sustainability.

Whereas, direct intervention in the reduction of environmental and natural resource inputs can be made by coupling with renewable energy systems, waste processing and energy extraction offer recycling of energy and resources.

Yet, central to this entire flow model is the habitat/building. It is both in the construction and operation of this habitat/building that energy resource flow can be optimized (Fig. 18).

Outlining the criticality of planning and design of the habitat/building, energy resource flow model becomes systemic basis for design. Wherein, climate-responsive architectural design and ecological planning become the determinants of energy resource flow and offer a powerful tool for optimization (Figs. 19 and 20).

Some Contemporary Solutions

One single parameter that embodies the state and use of natural resources in their various forms is energy. The author presents some contemporary solutions that optimize energy use/consumption through architectural design.

Design principles elicited from analysis of indigenous architecture and the scientific process of design have been translated into design of the following modern buildings at various locations in the country with diverse ecological context, outlining critical architectural responses to key issues.

How Do We Build in a High Altitude, Extreme Cold Dry Ecological Context?

Sustainable solutions for these projects incorporate the following elements and features achieved through architectural design:

- Architectural design optimizes solar exposure throughout the daily and annual solar cycle.
- Daylight distribution is optimized by three-dimensional configuration of the building and reflecting it off design elements: Light shelves and ceiling, providing a uniform and glare-free distribution.
- Embodied energy consumption in building construction is optimized by the use of local materials and relevant technology of construction.

Fig. 20 Energy resource flow–ecological footprint model.

Hill council complex, Leh, India

A major civic structure designed and built as architectural design solutions for this context (Figs. 21–25). Located at 3514 M above M.S.L. in cold dry climate with a severe long winter: October to March end (Min. DBT -30°C).

The main objectives and features of the design besides elements as sustainable solutions are:

- The complex has been designed for the severe winter period. Earth sheltering and earth-berming on the north side and a sunken lobby reduces northern exposure and stabilizes internal temperatures even in critical periods.
- Optimize solar heat gain to office and assembly hall during critical periods of the year, with adequate penetration of sun. While heat gain is optimized, its absorption in the judiciously designed thermal mass provides heat in the spaces over the diurnal cycle.
- Glare-free daylight to minimize lighting load, thereby consumption of energy in the building.
- A new expression of Ladakhi architecture by harmonizing indigenous with modern, incorporating local materials, has been created. This helps sustain the artisan and local art of construction also.

Fig. 21 Bird's-eye view of the complex.

What Possible Architectural Responses Can Be Evolved for a Composite Climate and the Context of Urbanity of Chandigarh?

PEDA office complex, Chandigarh, India

Located at Chandigarh, on a flat practically square site with no major topographical variations. Chandigarh as a city lies on the planes at the foot of Lower Himalayas, in a composite climate context.

- Here there are climate swings over the year, that is, very hot and dry period of almost two and a half months (Max. DBT 44°C) and a quite cold period of shorter duration (Min. DBT 3°C). The hot dry period is followed by a hot humid monsoon period (Max DBT 38°C and Max R.H. 90%) of about two months with intervening periods of milder climate.
- Equally important for Chandigarh is the context in space and time. Chandigarh, a bold experiment in city planning and architecture, was based on the professed ethos of design: Build with climate. Le Corbusier put into practice his theory on Brise Soleil. While the major buildings of the Capitol Complex extensively employed Brise Soleil in its various forms and applications, many residences designed by Pierre Jeanneret, Maxwell Fry, and Jane Drew made solar shading devices as a major element of design and expression. Yet, in its application both the method and device lack a scientific basis. Many times its repetitive use on buildings irrespective of orientation and the use of similar devices on different facade belie the claim.
- Can the design of a building be based on a scientific process of design, which responds to the ecological context and yet does not violate the urbanity of Chandigarh and its urban palette, that is, the material, texture, and color?
- That is the unparalleled professional challenge to which we have addressed ourselves.
- While the three-dimensional form of the building has been developed in response to solar geometry, that is, minimizing solar heat gain in the hot dry period and maximizing it in winters, to achieve a climate responsive building an innovative concept in architectural design has been developed. In place of the central loaded corridor plan stacked on top of each other to make various floors, which has virtually become the generic form for an office, the PEDA building is a series of overlapping floors at different levels in space floating in a large volume of air, with interpenetrating large vertical cutouts. These cutouts are integrated with light wells and solar activated naturally ventilating domical structures (**Figs. 26–32**). Consequently, the design is

thermally responsive to its climatic context and very good daylight distribution is achieved, thereby minimizing consumption of electrical energy.

Awards

The PEDDA building project has been awarded the Star Award several times ([Fig. 33](#)) and the Sustainable Architecture Exemplary Project Award ([Fig. 34](#)).

Conclusion

When we were designing and building this project, neither Griha Council India, nor LEED in the United States, existed. We were designing and producing good, meaningful architecture, which is what sustainable architecture is all about.

Fig. 33 5 Star Award by Bureau of Energy Efficiency as the most energy efficient building in the country.

Fig. 34 Sustainable Architecture Exemplary Project Award Griha Council, India, at TERI 10th 2018 summit.

What Can We Do With the Existing (Retrofit)?

There is the equally important issue of the existing stock of buildings that consume a disproportionate amount of natural resources in the form of energy in various forms. If by retrofitting we can render these buildings energy efficient, that will indeed be a great step towards sustainability.

Himurja building, Shimla, India: Limitations converted into opportunities

This perhaps is a befitting example of a solution in retrofitting and redesignation of use. A two-storied existing building being used for shops and warehouse use was handed over to us to be redesigned as a climate responsive building and converted into offices (Figs. 35–42).

- The building was redesigned as a four and half storied building with a hybrid R.C.C. frame (existing) and steel structure for the additional floors.
- Solar heat gain was optimized to all office during critical periods of the year, with adequate penetration of sun and protection from mutual shading achieved through architectural design.
- Glare-free daylight was used to minimize lighting load thereby consumption of energy in the building.
- Distribution of heat within the building is achieved through a double convective loop.

Can We Evolve a New Language of Ecological Architecture for an Innovative Institute?

The author was invited to participate in a limited competition for the above project (Fig. 38). An innovative architectural design evolving a language of ecological architecture presented by the author was selected by the jury for implementation of the project.

Fig. 39 Site/master plan.

Fig. 40 View from water-body.

Strategies for planning and design

- Control of microclimate of the site by generating a water-body drawn of the canal and by forestation of the site.
- Entire complex and each building designed as a climate responsive-solar passive building.
- Architectural design: The primary generator/tool for developing a low energy building design.
- Maximize environmental control through naturally conditioned laboratories and spaces.
- Maximize use of daylight to minimize electricity consumption in daytime.
- Couple evaporative cooling from water-body with building design.

Ecological architectural design of R&D wings

Since sophisticated R & D work is to be carried out in these wings, it is envisaged that three types of laboratories will be required, that is:

- Naturally conditioned laboratory
- Hybrid

Fig. 41 Solar chimney.

Fig. 42 Typical section through domical vault and solar chimney.

- Environmentally controlled through HVAC systems.
- The R&D wing has therefore been designed to couple the naturally conditioned laboratories and spaces to the water-body through wind towers coupled with earth tunnels to the laboratory and building spaces.
- Domical light vault designed for adequate daylight distribution integrated with solar chimney on domical vault coupled to wind towers.

Roof system

- The roof forms the critical element of the building design since it attracts the maximum solar heat gain and can be used as an element to generate efficient daylight distribution.
Hyperbolic paraboloid used as the structural element for the roof to:
- Optimize on structural design since this is the only doubly curved surface generated by a straight line, making it simple to construct since it generates only direct stresses.
- Double curved surface responds naturally to solar geometry cutting of solar heat gain due to summer sun and allowing penetration solar heat gain for winters.

Integration of renewable energy systems

- Solar chimneys integrated with building design for natural ventilation.
- Photovoltaic panels sandwiched in translucent panels on the south-facing central spaces for generating electricity and allowing penetration of diffused daylight.
- Water management system to be coupled with entire building complex for recycling of water and waste management.

Phase 1 of the project has been built

Photographs are not available yet.

Bamboo Structural Technology

Traditions and Rationale for Use

Though bamboo has been widely used in construction of ordinary houses and small structures traditionally, it has always been seen as the “poor man’s timber”, probably because of its being cheap and available, and being usually worked upon with less sophisticated tools as compared to carpenter’s tools used for timber. Bamboo is usually split, laced and lashed, rather than sawn, planed and nailed or bolted. The geometry of the surface that can be created with a bamboo framework is less true than that can be created with timber, leading to the larger possibility of leaks in tiled roofs when compared with timber. Bamboo treatment technology languished, practically non-existent, while developments in timber continued to dominate the building industry. This has created an unfortunate bias against the use of bamboo that persists even with modern techniques of construction described in this section. As with all such biases, bamboo has to often prove itself much better than industrially processed material in order to become accepted in the mainstream.

However, with increasing stress on timber resources globally and limitations on the felling of trees, bamboo has become an attractive wood substitute. As a wood substitute it is preferred to be supplied as treated and compressed sleepers rather than as poles, which is the more natural way to work with bamboo. With modern treatment and preservation techniques, the last quarter of the twentieth century is an era which can be termed as the age of development of engineered bamboo.

Bamboo, botanically a grass, represented by a thousand-odd species, is woody, strong, and very versatile in its applications. It is an abundantly available natural resource, especially in the tropics. Probably more significantly, it grows extremely quickly (at least in areas with sufficient water, even marshes), is tolerant of most qualities of water for its growth, and the plantations sustainably produce much more timber per unit area sown per year as compared to trees. Bamboo, being a grass, is amongst the fastest growing plants in the world. Trees can take 30 years to grow to the same height that a bamboo plant may achieve in just 90 days. Some bamboo species are known to grow even 90 cm in a day. Bamboo can be harvested in 3–5 years from its planting, which makes it a rapidly renewable resource.

Bamboo roots are strong and the clumps can hold soil and prevent its erosion. The fast growth of the plant utilizes carbon dioxide and releases oxygen, making it efficient in sequestering carbon. If we compare the carbon sequestering potential of bamboo with tree forests, the scientific opinion of their relative potentials is divided. While [Seethalakshmi et al. \(2009\)](#) argued for bamboo forests to be seen as a major climate change mitigation strategy, based mainly on their very large overall biomass productivity, recent studies in South America cited by the [National University of Misiones \(2017\)](#) point out that bamboo forests may even halve carbon storage in comparison to tree forests. However, all studies point out bamboo’s socioeconomic and soil conservation benefits.

Raw bamboo is abundant and extremely low cost, even after treatment. By way of example, a 50 mm dia., 4 m long, plain age graded pole of *Dendrocalamus Stocksii* in central India costs USD 2, and it doubles in price after pressure treatment with Copper-Chrome-Boron (CCB), while a roughly equivalent steel pole 40 mm dia. and 3 mm wall thickness of the same length costs USD 6 and if treated by galvanisation, USD 14. Thus, bamboo costs can be significantly lower than that of steel or timber. Therefore, the technology needs to be developed with the confidence that, barring a demand that outstrips supply too soon, this material might be a disruptive material for structures for the better part of this century.

Properties and Applications

Bamboo’s structural properties have been compared with steel mainly due to the fact that its mechanical properties per unit density are better than the same properties for steel. The maximum net density of bamboos is at most about 900 kg/m³ whereas steel has a standard density 8.72 times as much at 7850 kg/m³. Compared to that, typical values of strength of these two materials are summarized in [Table 1](#).

This simple comparison puts bamboo (per unit weight) higher than steel on important tensile and shear behavior properties. The poor figures on compression and bending are partly caused by the extra conservative factors of safety taken by the Code makers of IS 15912. All this doesn’t, of course, make bamboo “stronger than steel” as often claimed by bamboo apologists and the lay public, but definitely categorizes it as a very good natural material ([Awalluddin et al., 2017](#)) able to take considerable longitudinal compression and tension mainly due to the longitudinal bundling of its fibers. Bamboo also has reasonable ability to take bending compressions and tensions.

In any case, IS 15912 says: “Unlike timber, bamboo properties do not relate well to species, being dependent among other factors, on position of the culm, geographic location and age. The practice...to base designs on safe working stresses...may be

Table 1 Comparison of approximate design properties of natural bamboo with mild steel – taking poor properties for bamboo

	Density (kg/m ³)	Compression strength (N/mm ²)	Tensile strength (N/mm ²)	Bending strength (N/mm ²)	Shear strength (N/mm ²)
Poorest bamboo	900	10.5	~100	13.2	~20
Mild steel ($f_y=400$)	7850	260	400	350	160
Ratio bamboo/steel	11.5%	4%	25%	4%	12.5%
Ratio bamboo/steel per unit weight	100%	35%	218%	33%	109%

Note: Adapted from Wei Wen, D.T., 2015. The strength of bamboo in comparison with other construction materials. Available at: <http://danieltiongweiwen.blogspot.com/2015/05/research-question-how-does-properties.html> (accessed 20.01.19). IS 15912 2012 (17): Structural Design Using Bamboo – Code of Practice (Indian Standard Code by Bureau of Indian Standards).

adopted to bamboo with the limitations that *traditional experience rather than precise calculations* generally govern the detailing.” (emphasis added).

The strength of bamboo seems to lie in the silicone like outer skin that covers the culm, which therefore cannot be removed, but is unfortunately too smooth for it to be coated. Thus, most bamboo treatments are effected by hot dipping under atmospheric or higher pressure, so that the preservative material (often boric-borax or CCB, but also other materials) may steep into the fibers of the bamboo.

Due to its structural properties, bamboo can be used in a large number of superstructure applications in building and construction, for columns, beams, floors, roofs, etc. It can also be used for finishing, such as in floors, wall panels, and ceilings. Its limitations are a lack of sufficient research into the variability of its properties according to age, species, and other environmental conditions, lack of research on the performance of joints and junctions, its tendency to leach preservatives when exposed to rain, making it prone to attack by borer or fire, and, so far, its inability to provide the same level of “stiffness” as concrete when it comes to the fabrication of multi-floor buildings. Though bamboo exhibits borer infestation caused by the presence of eggs in the material as it grows, it is considered termite-resistant, which is a common misconception since termites thrive on woody cellulose.

Bamboo construction can be mechanized and prefabricated, making on-site installation very rapid and reliable. Some work to codify bamboo for structural use has been initiated in India and in California, and this area may probably develop rapidly with advances in development of bamboo structural technology in the coming decades. Until that happens, bamboo use remains outside the domain of “formal” structures and is used as an upgraded traditional material in areas where its use is common (such as Vietnam, parts of South America, parts of southeast Asia, and especially the island of Bali, Indonesia).

As a natural and rapidly renewable material, bamboo has the potential to replace both wood and industrial metals such as steel used in construction, after sufficient engineering advances have been developed and integrated into its harvesting, treatment, preparation and fabrication.

Forms

Bamboo can be used *whole*, or by laminating multiple slats of bamboo from wide-diameter and thick-walled species such as well-known Chinese moso (*Phyllostachys edulis*) to create a timber/board like workable material called *bamboo-wood* or bamboo strip-board, or by weaving strips into a mat and using them like timber veneers by hot pressing these into multiple thicknesses of bamboo mats or *bamboo ply* (this is generally better than timber plywood and board, being stronger, with better dimensional stability, smoothness, and resistance to humidity, fire and insects).

The following sections outline the forms and methods of use of bamboo in various building elements.

Foundations. Being an organic material, bamboo foundations are not recommended. Bamboo buildings are designed with conventional (masonry or concrete) foundations. Bamboo has been traditionally used as a pile material for driven pile foundations of buildings (similar to the wooden pile foundations of the Taj Mahal in Agra) as well as to prevent soil erosion along banks of earthen waterways.

Walls. The easiest and most common use of bamboo is to split low-diameter species and use half bamboo lashed into a grid as wattle and daub it (plastered on both sides) with raw or stabilized earth. This is a common type found in many low-income settlements in south Asia, and though very easy to make and affordable, these walls are not very durable, with a tendency to not resist flood and to decay by organic impurities.

Columns and beams. Traditionally, these have been erected with (untreated) whole bamboo with lashed or laced junctions, nailed or bolted together. In some modern applications, fiber-reinforced plastics have been used to cover lashed joints. The techniques for bolting and grouting junctions with a cement or concrete slurry pioneered in south America has allowed much larger spans to be attempted in the last few decades.

Bamboo columns and beams can be integrated into single structures displaying characteristically signature shapes, such that the difference between a column and its beam become meaningless, and the whole assembly may be considered a frame. Bamboo in a heated state is easier to bend to shape as compared to timber (even though it has a tendency to blow-back when released from its jig). This technique in fact has given rise to bamboo structures being *expected* to be curved in form in the minds of most commentators and critics, with single-curvature shapes (vaulted, arched, domed) or double-curvature shapes (shells, twisted surfaces).

Floors. Though the structure of a floor can be formed by trussing and framing techniques as developed for columns and beams above, the floor plate or covering or finish that is increasingly used in modern buildings (even mainstream ones) is bamboo strip-board flooring, which acts as an alternative to wooden plank flooring, with similar details. In traditional work, the framework was also covered by flattened, split bamboo culms or bamboo mats, though both do not create a fully sealed surface.

Roof coverings. Though the structure of a roof can be formed by trussing and framing techniques as developed for columns and beams above, the roof coverings can be made from halved bamboo large-diameter culms (used in an alternating up-down configuration, every alternate culm acting as a drain), or overlapped bamboo mats, or nailed shingles made of bamboo, slate or timber. For better class of buildings, a separate waterproofing layer is usually added below the shingles mats or culms. Roof coverings can also be formed by nailing chicken wire-mesh and steel weld mesh on the bamboo framework and slapping ferrocement on this armature.

Contemporary Technologies

Despite its remarkable structural properties, bamboo use has been greatly restricted to interiors, such as flooring and roofing elements and temporary structures. This is probably due to a perception bias about the material and lack of knowledge about its properties. Even assured practitioners may face difficulties in working with bamboo due to the natural variability of the material, vanishing local skills, a lack of thumb rules and guidebooks of structural design data and exclusion from building codes and manuals, but most importantly, the tendency for modern engineering to be based on processed, artificially manufactured materials as against natural ones because of their relative predictability in behavior.

While bamboo has been used for making houses and sheds for centuries, recent advancements in horticulture (such as the development and propagation of species that show very little nodal prominence, so geometrically more like poles) and treatment has allowed for a leap in architectural possibilities using bamboo. With the right kind of treatments, the right thickness of bamboo poles, complex joints made employing fiberglass and metals, bending technologies, and complex 3D-modeling using computers, it is now possible to create large span and multi-story structures using bamboo. Such practices can be observed across the world today from south American to southeast Asian countries. The method of design and construction adopted in each part of the world is unique, using locally available species, deriving from the local traditions and available technologies while being inspired by best practices around the world. Many case studies can be observed today where large span structures are built using bamboo poles that are bunched to create columns and frames for arches, vaults, domes etc. There have been experiments in low rise multi-storey structures in bamboo as well, with some remarkable examples in Bali.

Limitations

The above examples are exceptions though, and what holds back the widespread use of bamboo are some technical issues that still need much work from the structural and technical science.

Fire retardance. Since bamboo is a kind of timber, the tendency for the structure to catch fire is more. Though, like timber, it behaves “better-than-steel” in conditions of fire, retaining its resistance to forces over a longer period than steel, it is not easy to coat or encase in concrete to provide a fire-proof layer without losing its characteristic elegance. Hollow poles of bamboo also represent a high fire risk. Though the skin of bamboo stems create silicates that make it not highly flammable, this is often sanded off to create a smoother look for interior elements in a building increasing the fire risk. In exterior elements, the possibility of fire coatings and treatments leaching out of the material is real.

Fire prone-ness becomes even more critical in case of multi-storey and high rise buildings. In this context, the multi-storey timber code in Canada (that accepts buildings up to six storeys high) can be adapted to bamboo structures.

There is no standard practice to increase the fire safety in buildings. Around the world different practices are adopted such as filling the cavities with concrete, adding a panelling or plastering over bamboo elements to retard fire. The boron and boric acid treatments done on bamboo to increase the pest resistance also provide an added advantage as fire retardants. Recently, various proprietary fire resistant coating materials have been tried out on lightly sanded bamboo poles and provided good results.

Crack control. Bamboo has a round cross section, often with a variable internal and external diameter. This complicates the execution of joints between different poles since multiple drillings and tightening of bolts may be mismatched and may cause cracks in the vertical fibers. The heating and bending of bamboo may also cause cracks.

It is difficult to avoid these cracks unless the craftsmen working are extremely skilled and experienced. Because bamboo is mostly used in longitudinal stresses, in trusses and columns, often the cracks do not cause any structural disruption unless they are close to the horizontal nodes. It is difficult to ascertain the fatality of cracks since there is no set quality parameter for this and it may differ according to species, and on the function of said bamboo pole in the completed structure.

Brittleness. The Young’s modulus of bamboo is about one-tenth of steel (therefore making it poor even per unit weight compared to steel) and the linear portion of its elastic behavior is small compared to steel. Therefore, it deflects more and tends to exhibit sudden fracture, compared to a ductile material like steel. This limits its use until better research can be brought to bear upon the issue.

Natural Variability. Since the properties of bamboo may exhibit even greater standard deviation than other natural materials like wood, the concept of characteristic strength is not useful since these strengths may be very small as the standard deviation is high. What is required is to create standardized methods of harvesting and treatment by age and species, to bring the natural variation to acceptable limits (such as in timber). This area needs tremendous research work; however, Institutes of technology still treat bamboo as a secondary material and exhibit selection bias when it comes to topics for path-breaking research.

Design of joints. Bamboo joints are relatively untested and not standardized. Their structural performance, ability to withstand and transfer shear, compression, tension, or bending, depends on the species, age and conditions of the harvesting of the pole and treatment thereafter, the details and material of the joints, and above all the workmanship, thus making it a difficult issue to characterize. This area is expected to see a lot of expansion of research work in Institutes of technology.

Conservation of Material, Technology and Practice in Heritage Structure and its Relevance in Today's Context

Apoorva Dandge and Sheeba Valsson, Shri Datta Meghe College of Architecture, Nagpur, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

India has a large number of heritage structures made of different types of stone, brick, and plastering materials. Built heritage located in different parts of the country exposed to different climatic conditions in equally varied and each building material is affected in its own unique way. With the imminent need to cope with the conservation of heritage buildings, current knowledge though extensive is by no means complete.

India has over 15,000 historical buildings out of which ASI has declared 3570 buildings as national monuments and approximately same number has been declared by state governments as state important monuments and rest is being maintained by voluntary organizations, Wakf boards, Trusts etc. (Lakhani and Sharma, 2018).

Most of the heritage structures in India are in dilapidated conditions and main cause of their deterioration is environmental conditions.

Significant gaps still can be seen in the understanding of nature of restoration problem and their remedial measures. So far lime mortars have received less attention than that of the conservation of stone because lime mortar takes longer time to settle than cement mortar. In the case of restoration case People Place and Time should be of prime importance. This lack of attention leads to a series of unfortunate consequences which reduces the value and respect for the heritage. After closely observed mortar is the weakest link and easily reacts with the pollutants and other deteriorating agencies available in the environment. There is still significant gap in the understanding of nature of restoration problems and other remedial measures.

Understanding materials and the way they were used is crucial to the care and conservation of historic buildings. Traditional materials were often produced or extracted close to a building site, giving a strong sense of local identity.

Historical buildings are the most important ruins to describe history of a society. Historic buildings, which are the most important parts of our cultural heritage, must be best protected and repaired (Surlaker, 2018).

One of the key problems arising in the conservation field is finding materials compatible to the existing structure. Structures in India were mostly built in stone or brick masonry using locally available stones and mortars based on mud, clay and lime. Considering a dearth of the old material sources, craftsmanship and techniques, it becomes imperative to use new age available materials with properties matched to the ones used in the heritage structures.

Methodology

A Literature study was undertaken, to study the features and characteristics of the heritage structures in India. Case study of Sinhagad fort, Pune and Shahajanabad Gate, Bhopal, built in 2000 and 148 years ago respectively was undertaken to find out various material aspects in historic and present day context and with. A case representing change in the materials used for restoration of both the structure. Documentation and condition assessment of both the structure and comparative analysis on the basis of material has been done. Two cases from different regions with their past and present have been compared in this study. Analysis has been done on the basis of archival photographs, present day condition and various other elements to understand how authenticity criteria should contribute for the conservation of historic buildings.

Case Study Sinhagad Fort, Pune

Sinhagad is a fortress located roughly 30 km southwest of the city of Pune, India. Previously called as Kondhana, the fort has been the site of many important battles, Most notably the battle of Sinhagad in 1670.

It was also strategically located at the center of a string of other fort such as Raigad, Purandar and Torna. Perched on an isolated cliff of the Bhuleswar ranges of the Sahyadri mountains, it is situated on a hill rising 1312 m above sea level (Birodkar, 2008).

Given natural protection by its very steep slopes, the walls and bastions were constructed at only key places; it has two gates – the *Kalyan Darwaza* in the South-East and the *Pune Darwaza* in the North-East (Figs. 1–5).

Sinhagad Fort is greatly located atop on the Bhuleswar Hill range at an altitude of 1312 m. It is built on the plateaus of this hill peak. There is a full length of main ramparts surrounded on this plain land surface bordering its ridges. The fort is constructed of originally of Basalt stone which is locally available in the Deccan plateau fixed with the traditional material Lime mortar. There is a full length of main ramparts surrounded on this plain land surface bordering its ridges. It has got a very good defensive natural trench, since it has very steep slopes on major sides of this hill. These ramparts have two main gateways named as Pune Gate placed towards north-eastern side and the Kalyan Gate on south eastern side of this hill Rock. Few Hindu temples are also found here and the famous one is named Kaundinyeshwar temple. There are also few minor structures found in the ruined stages. The tombs of Tanaji Malusare and Rajaram are built here (Birodkar, 2008).

Fig. 1 Map of Maharashtra locating Pune. Source: <http://worldhindunews.com>.

Fig. 2 Plan of Sinhgad fort locating Pune & Kalyan Darwaja. Source: <http://trekshiti.com>.

Fig. 3 Image showing Sinhgad Fort, Pune. Source: <http://double-dolphin.blogspot.com>.

Sinhgad Fort being under the Archaeology Survey of India (ASI) property. No heritage Management Plan was prepared due to divided ownership and the area being extremely large to manage and to maintain therefore no such serious action were taken. Restoration of the Fort was done previously in the year 2013 and 2015 by the state archaeological department which did not meet the parameters prescribed to conserve a heritage structure leaving it in a dismal state even after faulty repair. The stone work was utterly substandard and inconsistent with the original work.

Fig. 4 Image showing Kalyan Darwaja. Source: <https://www.nativeplanet.com>.

Fig. 5 Image showing Pune Darwaja. Source: Author.

As no archaeological expert was involved in the restoration work no respect to the authenticity of the heritage was given which is why we can see the use of Concrete, use of inappropriate size of the stone, inadequate shape and Size of the battlement are seen (Figs. 6–8).

Architectural Documentation

Mortars & renderings are an important source of historical information which is insufficiently exploited, their study is neglected and original materials are often destroyed without preservation of samples and proper documentation. Proper documentation is the need of the hour. Fig. 9 is the documentation of the Pune darwaja and the staircase leading towards. Entire fort is constructed of basalt stone and lime mortar. Proportion of the stone vegetation Growth, traces of cement, missing stone were not taken into consideration during the previous restoration done in 2012 and 2015 (Figs. 10–13).

The site needs to be conserved considering the faulty aspects respecting the authenticity and integrity of the 200 yr old heritage. This fort is the major visitors' attraction good restoration should be kept intact the legacy of the Maratha Tradition through these old built structures.

Case Study Shahajanabad Gate, Madhya Pradesh, Bhopal

Bhopal the capital of Madhya Pradesh and so started the process of 'Development'. Large scale migration and big investments in the infrastructure suddenly transported this small principality into a town of National importance. The expansion was so fast and enormous that the original character and dace go got lost and marginalized in the process.

Location Shahajanabad Gate, Madhya Pradesh, Bhopal

Situated in the Shahajanabad area of the city, the construction of this edifice had been initiated by Nawab Shahajahan Begum in the year 1871 CE. This gate was constructed for the protection of Taj Mahal palace which served the grand entrance to the Palace. A three storied structure built with stone and brick is currently in a dilapidated condition (Figs. 14 and 15).

The original town was a conglomeration of six distinct areas, some of them with fortification wall with gates for entry and exit and Shahajanabad gate located in the Shahajanabad area, a fortified area was added to the main city. It consisted of gates, masjid, lakes, palaces and all. This 150 old heritage structure is restored with contemporary material and has lost the Authenticity and its heritage value. It can be well stated as the "Dying heritage of India" (Figs. 16 and 17).

The complete structure is plastered with cement whereas the interior of the structure is of the original construction constructed during the period of Shahajahan begum.

Stone Arch motifs in the Fig. 18 in the interior are constructed using sandstone and brick and bonded with the lime mortar. The base of the structure is constructed with stone and the above floor is constructed with brick and was plastered with lime mortar.

Fig. 9 Site plan Sinhagad Fort, Pune. *Source:* Author.

PLAN, PUNE DARWAJA,

Fig. 10 Plan, Pune Darwaja, Sinhagad Fort, Pune. *Source:* Author.

The structure today is completely ignored and human vandalism is the major cause of deterioration as at one period of time this served the main entrance to the Shahajanhnan Begum Taj Mahal Palace (Figs. 19 and 20).

When deteriorated, damaged, or lost features of a historic building it needs repair or replacement, it is almost always best to use historic materials. In limited circumstances substitute materials that imitate historic materials may be used if the appearance and properties of the historic materials can be matched closely and no damage to the remaining historic fabric will result. Survey of the defects in the building.

Analysis and Observation

Historical buildings are the most important ruins to describe history of a society. Buildings exposed to harsh effects of years and to natural disasters are generally under effect of very serious problems and they have risk of collapse and extinction. Historic buildings, which are the most important parts of our cultural heritage, must be best protected and repaired. The building materials play a decisive role in the behaviors of the structures they use. Historical agglomerations use different materials such as natural stone, brick, wood, mortar.

Understanding the two above case studies the use of lime mortar for plastering in historic structure's offers several advantages, specially a longer life to the structure, as has been proved by the longevity of historic building and monuments.

Fig. 11 Trace of concrete and vegetation growth in the staircase. *Source:* Author.

Fig. 12 Images showing damaged stone. *Source:* Author.

Lime is natural occurring, less susceptible to ageing and adjusts to temperature variation and is also less prone to cracking. The lime mortar allows the structure to breathe due to its porosity and permeability and hence maintain the temperature and reduces dampness and other problem. In this particular above case study lime mortar is used as a binding material which a traditional technique and material. The main reason for not using lime as a binding & plastering material is the time constrain. Use of Traditional materials takes longer time to set as compared to cement mortar, other such factor is Workmanship, as it is the physical material and construction technology has lost its importance due to less availability of time and skilled workmanship which is therefore the result seen in the above two restoration.

Case Study 1: Observation

Detriment and Distortion in Structure

Damaged masonry

Before the restoration of the fort wall the exposed stone masonry was found to be damaged with gaps, cracks running along the length of the fort. Layers of mute was the exposed stone masonry and remains of the original plaster surface are found to be covered with layers of white wash and cement plastered. Extensive use of cement for fixing of stone and plasterer has been used to restored the fort wall. The missing stones are not fixed and is still in poor condition (Figs. 21–23).

Fig. 14 Map showing location of Bhopal. *Source:* <http://office.incometaxindia.gov.in>.

Fig. 15 Plan showing location of Shahajanabad Gate, Bhopal. *Source:* <http://www.spaenviis.nic.in>.

Case Study 2: Observation

This particular front elevation depicts the use of cement plaster in the structure whereas originally lime plaster was used. Due to this intervention Authenticity of the structure has been reduced though the Gate is structurally stable in present condition. **Fig. 24**

Fig. 16 Archival image, Shahajanabad Gate, Bhopal. *Source:* National Archive of India, Bhopal.

Fig. 17 Present condition of Shahajanabad, Bhopal. *Source:* Author.

Fig. 18 Stone arch Motif, Shahajanabad Gate. *Source:* Author.

Fig. 19 Brick Masonry with cement plaster. *Source:* Author.

Fig. 20 Arch detail. *Source:* Author.

Fig. 21 Vegetation growth in the stone wall. *Source:* Author.

depicts the condition of the structure before Restoration. The structure was in dilapidated condition with exposed masonry, flaking, Algae Growth, Black water stain which was reducing the structural strength. The Restoration was done by using cement which managed to withstand the strength of the structure but lost its identity. Conservation of Heritage structure has a certain process in which it has to match conserving parameter which this structure has not achieved.

A documentation study was done in each of these case studies for understanding the seven criteria of Authenticity which are:

- (1) Location
- (2) Design

Fig. 22 Missing stone, Fort Wall. *Source:* Author.

Fig. 23 Damaged masonry, Fort Wall. *Source:* Author.

Fig. 24 Condition assessment of Shahjanabad Gate, Bhopal. *Source:* Self.

- (3) Setting
- (4) Materials
- (5) Workmanship
- (6) Feeling
- (7) Association.

Out of the seven criteria of Authentication Material criteria was discussed mainly by documenting the two heritage structure in different regions of India.

Whereas location refers to the specific place where a property was built or an event occurred, setting refers to the character of the place in which the property played its historical role. It involves how, not just where, the property is situated and its relationship to surrounding features and open space E. Function/Use Is the degree of continuity of original or significant uses in a property. An

Table 1 Material analysis

Sr. No	Case study	Age of the structure	Original construction material	Restored building material
1.	Pune darwaja, Sinhagad Fort, Pune	2000 year old	Basalt stone with lime mortar	Restored using cement mortar
2.	Shahajnapad Gate, Bhopal	150 year old	Brick and stone with lime mortar	Cement concrete

Source: Author.

historic area and its surroundings form a coherent whole including associated human activities and constructions; continuation of original or compatible uses minimizes negative impact on authenticity.

The material criteria state that the physical elements that were combined or deposited during a particular period of time and in a particular pattern or configuration to form a historic property. The choice and combination of materials reveal the preferences of those who created the property and indicate the availability of particular types of materials and technologies. Indigenous materials are often the focus of regional building traditions and thereby help define an area's sense of time and place (Alho and Morais, 2000).

Following the above criteria for authenticity material condition assessment and its relevance in today's context was studied following is the case study analysis (Table 1):

Conclusion

The most common reason for considering substitute materials is the difficulty in finding a good match for the historic material (particularly a problem for masonry materials where the color and texture are derived from the material itself).

For example, the same material shall be no longer be in operation so all efforts should be made to locate another material that could supply a satisfactory match. Care should be taken to ensure that the detail, color and texture of the original material are matched and no visual differences should be seen.

Great care must be taken if substitute materials are used on the exteriors of historic buildings. Only after consideration of all options, in consultation with qualified professionals, and development of carefully written specifications should of any conservation work is undertaken.

The use of local materials and traditional technologies must invariably be preferred and respected. Decision must be founded on the accessibility and the availability of traditional knowledge systems. Modern substitutes should be considered only after their use is proven efficient and judicious, and must not compromise the integrity and continuity of local building traditions.

Rehabilitation of old buildings with historic significance is different compared to normal repair of concrete structures as the materials used in construction are natural and the restoration is to be done by maintaining the architectural aesthetics and ambience. One should be able to blend new materials with old building materials. It should be borne in mind that primary responsibility is not only to regain the architectural aesthetics respect the old buildings perform their new roles for future generations.

Constructing a PV-Integrated Permanent Bamboo Building – An Experience

Madhumita Roy and Saroj Mandal, Jadavpur University, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Bamboo is a low-cost building material, widely available in the world; it is lightweight, durable, flexible, and easily cultivated and processed. The use of bamboo as a structural material is well-known in constructive traditions. Bamboo construction is mainly associated with poor rural housing as a low cost alternative building material. The bamboo has appropriate structural and mechanical properties and high strength/weight ratio. In its natural form, it has a high moisture resistance and is widely used for flooring as well as in making furniture also with some modification. Moreover, the capability of protecting the environment, due to its sustainability, is a relevant aspect to consider and its ability to mitigate constructive emergencies in developing countries. However, with the advent of a new era of exploring the traditional building materials, it became an important area of research to use the bamboo as permanent cost-optimized, energy efficient solution to mass housing projects especially in regions where seismic activity and cyclonic weather is a threat. Despite of its enormous potential, it is still not considered as a permanent building material in most countries.

The National Mission on Bamboo Applications (structured as a Technology Mission) is one of the key initiatives of the Department of Science & Technology (DST), Government of India for enhancing the bamboo construction sector, towards augmenting economic opportunity, income and employment generation. It may be mentioned here that in India, more than 100 species of bamboo grass are available out of which few species are of solid nature and the majority are of hollow types. Though it is an accepted fact that Bamboo is an exceptional structural material but in absence of appropriate design guidelines, its acceptance as an permanent building material is not well recognized. The research project under TIFAC (Technology, Information, Forecasting and Assessment Council), from NMBA (National Mission on Bamboo Application), government of India embarked upon the intention to justify the feasibility of a bamboo structure and to include the different parameters in the different standard. It may be mentioned here that the use of bamboo as a natural construction material is also regulated in several countries by specific standards. Finally an attempt has been made to enhance the prospects of use of bamboo as an alternative mass scale permanent building material as a cost effective, environment friendly as well as esthetically appealing. The latest version of National Building Code has included the general principles involved with the Bamboo construction in its Subsection 3B of Part 6: Structural Design – Timber and Bamboo ([Fig. 1](#)).

Fig. 1 Samples prepared for lab testing.

Fig. 2 The site after clearance.

Site Location and Features

Due to severe space crunch within the campus of Jadavpur University, a damping ground near the Guest House has been taken for the experimental project on a building made up of fully using structural bamboo considering the architectural and structural features. The site (**Fig. 2**) had several fully grown trees along with a few shrubs and samplings leaving limited space for construction, which became a cause of concern. Also there were limitation on the visibility factor and the lack of sense of arrival for the location. The streets approaching the site were narrow and the surrounding areas were cloistered with 3–4 stories building which further deteriorated the sense of place for the building. But the most impressive quality of the site (**Fig. 3**) was rendered by the presence of the water body in its proximity. The water body added to the much desired break of monotony. All these factors had been thoughtfully addressed in order to ensure that the effort that went into conjuring up the new architectural vocabulary was not lost to the banality of the surroundings.

The adjacent guest house mainly houses the Faculty Club, a place for refreshments. It is also regularly used to host seminars and conferences also. The guest house rooms are also under considerable use owing to the proliferation of academic conferences at the University. Being located next to the University Guest House, the project posed immense opportunities but also had several functional issues. The dilemma had been about the kind of functions that could be incorporated to this new experimental building that could adduce the functioning of the guest house but also be an important point of academic discourse in terms of architectural genius. The functions of rooms for the guest were thought to be a tad bit trite for the new building. Again, there were other issues of safety has been considered. Finally, it was decided that the new building would not only be a paradigm shift in terms of building materials, but would also be an innovative way of showing the limits of the material. A multi-functional building was suggested that could also address to the esthetic value of the building. A fully functional seminar facility and an extension of the Faculty club were decided upon (**Fig. 4**).

Architectural Paradigm

The project involves design of a stilted two storied demonstrative bamboo structure with simple innovative bamboo joineries and local techniques to enable engagement of local semi-skilled workers for such construction. The idea was to use locally available bamboo species to enable widespread acceptance and to create a built form of high esthetic standards which can be rendered as an attractive liveable space consequently leading to greater acceptance by the masses. The project also aimed to test the durability of the bamboo boards as well as the performance of the whole bamboo sections as permanent structural building material. The whole building appears to be a single one but horizontally it is divided into three parts and vertically into two levels. The purpose

Fig. 3 The site plan.

Fig. 4 The Bamboo Building-the way it was conceptualized.

of the horizontal division was to carry out experiment of three types of foundations with bamboo and the differences in levels were done mainly to carry out energy related experiments (Figs. 5-7).

The whole bamboo poles are left exposed to enhance the esthetics, lending a natural aura to the space while the free flowing interiors merge seamlessly with the outdoors and the huge water body lying on the rear portion of the site. The fenestrations were

Fig. 5 The Bamboo Building under construction with thatch roofing.

Fig. 6 Hollow pipes inserted into concrete base.

designed very carefully to create intricate, light-filled building. The landscape was done consciously displaying all local varieties of bamboo available in the region. The interiors need not require any further touch up other than placing some bamboo furniture & fittings ([Fig. 11](#)).

Structural Aspects

The whole building is designed and modeled as a frame-structure with bamboo columns and bamboo beams. All typical load like Dead Load, Live Load, Seismic Load and Wind load has been considered in the design process. Each of the column and beam is

Fig. 7 Column details.

made up of four inter connected whole bamboos. The interconnection has been made with bamboo also at a suitable spacing. The spacing of the main bamboo is fixed based on the design load applied. The floor is consisting of commercially available bamboo board resting on beams. Based on the capacity of the bamboo board the spacing of the beams has been fixed. The columns are also braced with bamboo member to strengthen the structure against lateral load like wind and seismic load. The ground floor of the front portion is stilted at a height of 600 mm so that the portion below the floor can be cleaned easily. The Ground floor is completely open with no walls and thus the air allows the house to catch every breeze that comes through. The structural grid was chosen in such a manner so as to accommodate the 2400 mm × 1200 mm bamboo boards as flooring material on whole bamboo beams (Fig. 9). The central portion is frame structure which is resting on a sand bed. The rear portion is entirely with bamboo board with brick foundation. Two toilets are placed in this rear portion at ground floor level and the pantry is at the first floor level. The first floor of the front and the middle portions are covered with wall panels made of bamboo boards. The boards used in the western and southern facades are insulated ones. The roofs are designed at different angles suitable enough to have covering with both thatch and solar panels for two specific reasons; (1) to protect against rain (2) to give a good esthetic appearance.

The foundation of the structure is designed as typical isolated footing type (refer Figs. 8 and 9). Size of the footing is fixed at 1200 mm × 1200 mm for each column. Four steel tubes of diameter 150 mm is inserted in the isolated footing at a spacing of 500 mm within the pedestal of size 900 mm × 900 mm. The four bamboos used in a column are inserted in the four steel tubes.

Fig. 8 Details of inclined column.

Fig. 9 Bamboo boards inserted into the pillars.

The gaps between the tube and the bamboo have been filled up fly ash or sand and finally sealed with sealant M-seal or equivalent. The bamboo is connected to the steel tube by 12 mm diameter pin. The tube is connected to the footing with foundation bolts of 16 mm diameter with four angle section. For inclined columns the tubes are inserted in inclined position (**Fig. 8**). All the materials used in the building are of low technology and easy to apply. Different types of joineries were explored, prepared and the testing were carried out in the lab before its actual application (**Fig. 1**). Examples of bamboo usage in the present structure as a composite material demonstrate its full potential as a structural and environmental friendly material. Finally the set of plan schemes from the presented project is an attempt to transfer the technology into the practical applications, offering suggestions for possible destinations.

A 'Zero Energy-Zero-Waste' Building

This research project aimed to be a 'zero energy-zero-waste' demonstration project for students, professionals in the country. A 20 kW grid connected solar PV integrated roof (**Fig. 10**) has been installed replacing the thatch roof under the funding of MNRE

Fig. 10 Integration with solar.

Fig. 11 Solar lanterns.

(Ministry of New and Renewable Energy) through WBREDA (West Bengal Renewable Energy Development Authority) in the phase-II of the research project to reduce the dependence of conventional power. Bamboo was chosen as the main material because, as a natural resource that fixes carbon into the soil and also minimizes CO₂ emissions throughout the whole production phase (Fig. 11).

Conclusion

The application of the proposed technique of construction is not exclusive for developing countries. It can be also adopted in all the areas with environmental and technological features for the use of bamboo. Further investigations should be conducted to protect the façade walls (here not considered) from the risk of rocking falls from the movements of the roof, as in due to earthquakes. It will be carried out on additional structural schemes and corresponding experiments constructions, in view of its eco-friendly characteristics. Moreover the structural system involves only natural materials (bamboo canes, plywood plate, wooden pins, canapé ropes) with strong reduction of environmental impact in those areas where the natural materials are available.

Acknowledgment

I sincerely extend my gratitude towards the then Vice Chancellor for his outstanding support and encouragement by allowing us to carry out such a difficult experiment in an institutional set up. Acknowledgments to all the research fellows of the 'Energy Efficient Built Environment' Lab and students of the Department of Architecture who have worked in the project from time to time for their tremendous effort in implementing the project. Also, I would like to thank all the staffs of Jadavpur University for rendering so much support during the implementation phase of the project.

Energy Efficiency and Thermal Comfort in Heritage Buildings

Anjali K Sharma, School of Planning and Architecture, Delhi, India

Introduction

Energy is a major factor for development. The building sector is the highest consumer next to transportation, followed by others in the cities, and requires an uninterrupted supply of energy. These consume about 75% of global primary energy and emit between 50% and 60% of the world's total greenhouse gases. In 2012, the global energy supply consisted of 81.3% fossil fuels (oil, coal, and gas), 9.7% nuclear power, and only 9% renewable energy sources (such as hydro, wind, biomass, and solar). Unfortunately, this widespread use of fossil fuels causes a number of challenges. Carbon-based energy generation has a large ecological footprint, not only due to rising greenhouse gas emissions and pollution caused by burning fuels, but also because of extraction techniques that contaminate the environment, and frequent production or delivery accidents (see "Relevant Webiste section").

With limited energy available on the planet *efficiency* is crucial. Energy is required for its production, transporting/transmissions through grids (nature and type of grids) to consumption for lighting and appliances (use of level of technology) and related losses and emissions that add to the GHG gases and carbon emissions at large. The concern is actively addressed for new construction but the existing old buildings especially with heritage value are a challenge. These building stocks are a huge resource of sociocultural connotation, and thus a sensitive issue to be attended with care.

Energy Consumption in Buildings

By 2050 68% of people are expected to be living in urban areas [UN], which means the necessary building stock should be in place, and if it is not energy efficient the implications will be far-reaching globally. Energy consumption is essentially governed by:

- Climate: Parameters: geographical location, water, temperature, humidity, and features of land.
- Climate responsive building design: Thresholds of thermal comfort/standards/norms, local, regional, and global.
- Building performance, technology, and behavior changes, social connotation.

Further due to global warming the need for cooling is on the rise globally. Use of air-conditioners/central cooling or heating affects the microclimate too, largely seen in cities.

Cities account for 75% of total global energy demand and produce 80% of our CO₂ emissions, driving climate change. This figure rises to approximately 80% when the indirect emissions generated by urban inhabitants are included. Buildings also consume vast amounts of energy at all stages of their existence. Energy is needed for the raw materials, construction process, and maintenance and daily operational needs such as lighting, air conditioning, and cleaning. In addition, urban sprawl, increasing distances between destinations, and inefficient public transport systems prompt overall reliance on private motorized transport, such as cars, which have a high energy consumption, mostly of petroleum products (see "Relevant Webiste section"). With urbanization energy consumption shall rise due to the planning and building sectors. Also with the high rate of urbanization in Asian and African cities the implications are far-reaching, as the built-up areas required in these cities are huge. Further, being closer to the equator, the demand for cooling for thermal comfort shall be equally high but the hope is there if the building stock is built in a sustainable manner (Dulac and Hinge, 2016). Currently global use of energy in buildings has grown by 1% per year, global use of electricity in buildings has grown by 2.5% per year, and global building-related CO₂ emissions continues to rise by nearly 1% per year (Dulac and Hinge, 2016).

Energy Efficiency and Thermal Comfort

With limited energy available on the planet *efficiency* is crucial. The law of thermodynamics clearly states that energy can neither be created nor destroyed but *only* can be changed from one form to another, clearly reinforcing the limitation. Thus efficiency is the key word. In buildings thermal comfort followed by lighting are major energy consumers irrespective of the type of building (Figs. 1 and 2). Typically the energy consumption in buildings is due to heating and cooling, followed by illumination or lighting, irrespective of the type of building (D&R International, Ltd., 2011) (Fig. 3).

To achieve energy efficiency there should be a three-pronged approach: (1) to reduce the demand (Gupta and Gregg, 2018) being the foremost followed by (2) optimum consumption of energy and (3) consumption within the limits of energy produced by renewable sources only. Such an approach reduces the carbon emissions and moves towards net zero and sustainable development at large.

Often the norms and standards in the developing nations are not in place and invariably not updated for technology as it is getting updated regularly making the execution of buildings and the building envelope too. Delay in implementation and enforcement of building envelope measures results in additional energy consumption. Building performance evaluation studies too are integral to improve on the design and detailing of buildings. Cooling is the fastest growing use of energy globally and thus

Fig. 1 Global map floor area additions by 2025 (in billion square meters). Source: IEA.

Fig. 2 Residential buildings energy consumption by end use (2010). "Other" includes small electric devices and heating elements.

the focus on air-conditioning. Energy efficiency improves energy security. Typically appliances and building equipment typically need to be replaced every 15 years or so as buildings' major source of GHG.

Energy and Heritage Buildings

Typically, historic building stock was built next to available natural resources: Water and landforms that provided security. Thus the heritage buildings are indigenous to the locally available resources and therefore the desire to be authentic at the expense of the local was not the norm. Most of the traditional heritage built environs were governed by frameworks outlined in ancient scriptures and texts in various cultures that acknowledged natural resources, and are strongly reflected in our heritage buildings in planning and detailing. For example: Ancient Indian concern for environmental protection is found in Kautilya's "Arthashastra." It was the Dharma of each individual in the society to protect nature. People worshiped natural elements: Sun, air, water, and land. Thus recognition and acknowledgment led to protection and preservation of the environment. Similar ideologies are also depicted in Buddhism and Jainism, which propagate nonviolence, minimum destruction of natural resources, and simple living with minimal needs (minimum consumption of energy). While Muslims and Christians consider water sacred and pure. Such a backdrop

Fig. 3 Commercial buildings energy consumption by end use (2010). “Other” refers to miscellaneous sources like medical equipment, ATM machines, and telecommunications.

outlined a framework of development that respected the natural resources and optimum use of them was integral. But currently the high rate of urbanization coupled with the nature of development ignores the traditional approach; also fast construction facilitated by technology uses the resources quite indiscriminately.

Considering urbanization is a historical trend. Historic records indicate that cities existed over 8000 years ago. Important urban centers developed around the 13th century with the Silk Route stretching halfway around the globe, from Italy through Central Asia, Mongolia, to China and Japan. It left behind a precious strand of heritage cities, including Samarkand, Bukhara, and Kaifeng.

With the Industrial Revolution cities experienced exponential growth setting up so-called modern lifestyles, standards, and norms of city life. This assumed the status of the contemporary lifestyle the world over and governed development across the nations, and this deviation from the contextual living has accelerated climate change and is not sustainable. In Jay Inslee’s words “we are the first generation to feel the impact of climate change and last generation that can do something about it.”

Interestingly the global south, where the majority of the development is expected to occur, has the bulk of existing heritage and thus its relevance, contribution, and learning cannot be negated. In fact the World Urban Forum’s six big ideas recognizes that the integration of Historic Urban Landscape and Values (HUL)-based community values in the planning and design professions is fundamental.

Current Status of Heritage Buildings

Heritage buildings are a huge resource of contextual building frameworks that are environmentally friendly and thus sustainable. But the perception of the heritage environs by the architects and planners is to view them as a page of history and thus addressed as such: Either as a conservation project by a set of professionals or as a dimension of issues in planning exercises – A layer acknowledged but not necessarily integrated in the planning at large. However, they are a strong contextual resource with time tested solutions for design, planning, and construction. Seldom are they integrated such in mainstream design and planning, considering these contextual approaches typically demonstrate a strong relationship with nature underpinned by local cultures that have had minimum impact on the environment and thereby climate change. Further they had a distinct identity of their own that is significant from a sociocultural point of view, enabling people to connect to their roots, bringing in harmony and well-being in societies.

The heritage buildings stocks in various countries have a distinct take based on their socioeconomic status, as environmental degradation is uniform to all. Where these economies are strong they are preserved, often conserved as cultural landscapes. While in some cases where they are in abundance with developing economies they act as resources and used through revitalization, adaptive reuse, additions and alterations, etc. essentially based on their heritage value: Age, architectural style, elements, features to design, and planning merit. Sometimes if the location of the heritage structure is strategic in the city, then it is even demolished, a permanent loss.

Unfortunately heritage buildings are looked upon by the city planners and architects either to be preserved or conserved as such. But they are a timeline layer in the planning of a city/place and need to be acknowledged as such and integrated as another dimension of design in developing city plans. The current parallel approach inhibits the heritage buildings from being mainstream assets.

Characteristically each heritage building has a framework of development as follows:

- **Site and surroundings:** The framework of development based on the respective cultures governs location of each building: For public buildings adequate open spaces to account for spillover activities and others. Further based on the nature of building proximity to water, sociocultural issues were addressed. The topography of land, flora, fauna, and other natural features are acknowledged and retained as such, essentially in line with the environment. Next manmade structures especially related to religion, having significance to local communities, are integrated in the overall planning and resultant sites selected for use.

- Design principles: Typically the sociocultural connotations governed the design and planning of buildings; thus the spaces delivered over and above the functional aspect. Often the texts and literature specific to the communities abided by, for example, orientation, distribution of the built mass with respect of the open spaces, scale proportions, and systems at large. Such an inherent discipline structured the design and planning at large making it in harmony with itself rather than an architectural feat for a building. Therefore the heritage buildings are intrinsic to the development or city's fabric.
- Selection of architectural style: Archetypally each of the historic buildings are distinct for some land use type. All dimensions of space, from its disposition, spans, and relationships between covered and open, system of fenestrations, scale proportions, order in section, and elevations of the buildings. As most of the historic buildings were built when public infrastructure services were not in place, invariably they utilized daylight judiciously and thus were low on energy consumption even for the standards of today. These buildings were designed with passive systems for thermal comfort, and were fairly effective thus energy efficient by nature, as the cost of air-conditioning is high in buildings. From structural systems to embellishments the architectural style is insightful.
- Choice of building material and technology for its execution: Conventionally the selection of building material was what was locally available, as that proved to be environmentally friendly with no transportation costs and was in line with the natural environs. The context played a crucial role in determining the choice of materials that were locally available, and technology was often indigenous thus environmentally friendly and often low on energy as well, as when these technologies were in place in history they were labor intensive, unlike current technology that uses energy.

This clearly enumerates the holistic approach that contributes for energy efficiency and thermal comfort addressed within the sociocultural milieu, a significant measure for well-being.

Heritage Buildings: Energy Efficiency and Thermal Comfort

All heritage buildings are strongly contextual thus the framework of development too is contextual, implying also indigenous and localized thresholds and norms. Use of passive systems was a predominant design criterion for most of the buildings, for example, based on the geographical location and climate typology; the locally available material of requisite due thickness for walls was selected, for example, for a hot and dry climate, if the locally available material was stone, then based on its characteristics the wall thickness was decided. If it was adobe, then thickness was revised to have adequate time lag to ensure the transmission of heat indoors. Further, the outer surface was finished to reflect maximum heat or vertical surfaces protected with deep overhanging projections so that direct heat was avoided.

The fenestrations openings too were detailed such that in a hot and dry climate, if there were strong winds, then dust would be a concern for which the size of openings should be minimum and small; also the shape had to be with maximum area with minimum perimeter (for example, a circle). But for thermal comfort movement of air is important, so there should be a number of openings with a certain hierarchy of openings to ensure such air circulation and take into consideration basic principles like hot air's tendency to move upwards, leading to high ceilings for habitable spaces. Additionally the most efficient system of fenestrations became integral to the architectural style of that place, eventually contributing to the heritage buildings' identity. Such approach was used for the roof and intermediate floors, thus ensuring the least energy demand for the building. Selection of locally available material by default defined the spans and structural systems for roofing but wherever large spans were required then technology was resorted to, while some of the indigenous solutions were strongly contextual; this reduces the energy for transportation while spans assure optimum energy use. The construction technology used was labor intensive; although time consuming, it was environmentally friendly. Extensive use of lime is labor intensive, fire resistant, and termite resistant; it can be used for foundations/roofing/mortars, with time weathers into a strong material, consumes much less energy when compared with concrete; and is biodegradable as well. Also the thermal properties are such that for certain climatic conditions it makes indoor spaces thermally comfortable. Next, design fundamentals like symmetry, compact development, perimeter blocks, etc., make sure that the energy demand is limited.

Similarly for various climatic zones heritage buildings demonstrate such features for thermal comfort and energy efficiency at large. Therefore significance of heritage buildings cannot be negated; unfortunately not many studies have been conducted to document such empirical data. One of the main reasons may be because most heritage buildings are in Asian countries, which have extremely low research bases coupled with poor economies.

Conclusions

The global concern of sustainability and climate change over the last three decades has picked up momentum, essentially becoming the need of the hour. Developing Asia can make a significant contribution to global efforts to reach the objective of the Paris Agreement, which is to restrict global warming to well below 2°C urbanization in Asia: Energy Efficiency Initiative and Sustainable Transport Initiative (ADB, 2017). Although various continents are at varying stages of development, with Asia urbanizing the fastest it ever has, the issue is very crucial.

Considering civilizations have been centuries old, cities were built inhabited few still continuing; it is interesting to note that centuries old cultures that shaped up civilizations sustained for so long. Thermal comfort has always been the foremost concern for habitable spaces and heritage buildings have demonstrated that through their respective solutions: Which meant that the construction of building design responded to the respective climate, and this may be interpreted as a framework of the context. Thermal comfort through energy efficiency can be achieved with wisdom that hinges upon traditional knowledge while the technology base upgraded with time can be gauged with empirical data. Thus it can be now scientifically argued through climatic responsive building design to energy efficient building design; in essence both address the issue of thermal comfort of inhabitants indoors.

Environmental Life Cycle Analysis of Earthen Building Materials

Ricardo Mateus, Jorge Fernandes, and Elisabete R Teixeira, University of Minho, Guimarães, Portugal

© 2020 Elsevier Inc. All rights reserved.

Introduction

The building industry is one of the largest consumers of natural resources, both renewable and non-renewable, being responsible for almost a third of all carbon emissions and for consuming more energy and raw materials than any other economic sector (Mota *et al.*, 2012).

During the last decades, architecture has been based on the use of industrially-produced materials, with a low thermal resistance, e.g., large glass surfaces, making buildings extremely vulnerable to outdoor temperature fluctuations. The result was the construction of buildings with a high level of dependence on air-conditioning systems to ensure adequate indoor comfort conditions (Petter, 2011), raising the significance of the building sector in the overall energy consumption. Beyond this, industrially-produced materials are normally produced through energy-intensive manufacturing processes and have considerable environmental impacts, while natural materials, such as timber and earth, normally have low or neutral potential environmental impacts in a life cycle perspective (Mota *et al.*, 2012).

Modern buildings generate important externalities on the environment at local, regional, national and global scales (Ingrao *et al.*, 2018). Nowadays, energy efficiency and sustainability of buildings are important research issues. In the life cycle assessment of buildings, the environmental impacts linked to all life cycle stages of products are estimated (Ingrao *et al.*, 2018). One of the environmental parameters of major relevance in this assessment is the Global Warming Potential, related to greenhouse gases (GHG) emissions, in particular, carbon dioxide, which is closely related to the operational energy consumption and embodied energy of building elements (Stephan and Stephan, 2016). Embodied energy is the amount of energy used to manufacture, transport, assemble and maintain the different building elements, from cradle to the end of the life cycle. The operational energy is the energy used in heating and cooling systems, lighting and in the operation of building's integrated systems (Stephan and Stephan, 2016). To achieve a carbon neutral built environment, it is necessary to optimize both the embodied and operational energy (Dixit, 2019). Nowadays, most of the focus to reduce the life cycle energy consumption in the building sector is put in increasing the energy efficiency during the operation phase. For instance, the European Union is promoting the construction of nearly Zero Energy Buildings (nZEB), by targeting that by 2020 on all new European buildings must be nZEB. While buildings become more energy efficient during the operation phase, the importance of the amount of embodied energy in the life cycle energy balance is increasing, thus pushing the need to find alternative materials to those with high embodied energy (Ramesh, 2012) and more efficient manufacturing processes.

The life cycle assessment (LCA) method allows the evaluation of the potential life cycle environmental impacts and of the total embodied energy of a product or service. The implementation of an LCA study in the product stage is very important since it allows evaluating which are the processes with higher impact and how changing them can contribute to improving the environmental performance of the product. One way to communicate the results from an LCA analysis is to develop the Environmental Product Declaration (EPD) of the product under study. EPDs follow a business-to-business communication format but can also be used by architects, engineers, owners, constructors and consumers to support decision-making in the choice for products with lower potential environmental impact.

In Portugal, it has been estimated for a conventional building (with a lifetime of 50 years) that the embodied energy in building materials is about 6%–20% of the total energy consumed during the buildings' life cycle (Mateus *et al.*, 2007). Additionally, the study carried out by Mota *et al.* (2012) has shown that materials like ceramic tiles, concrete and alkyd paint are the ones that contribute most to the overall life cycle environmental impacts. In this sense, reducing the embodied energy in materials is a premise to reduce the environmental impacts and achieve more efficient and sustainable buildings. It can also contribute to decreasing the cost of materials and in particular of the life cycle cost of a building as a whole (Ramesh, 2012).

Using alternative materials and techniques, like the vernacular ones (lime, earth, adobe, vaulted ceilings, etc.), it is possible to significantly reduce the total embodied energy of a building, as well as the environmental impacts (Fernandes *et al.*, 2013). Understanding that construction materials have important environmental impacts, vernacular materials have, from the sustainability point of view, several advantages. Usually, the most environmental advantages related to this type of materials are: no need for transportation, since they are local materials; lower energy-intensive production processes; and, consequently, lower embodied energy and CO₂ emissions. Furthermore, they are natural materials, often organic, renewable and biodegradable, with better adaptability to the local climate conditions and durability, allowing to improve the environmental performance of a building also in a cradle-to-cradle approach (Singh *et al.*, 2011).

Besides the environmental advantages, these materials allow for social and economic benefits. The local production of materials is not only economically cheaper but also creates jobs (Fernandes *et al.*, 2013). The need for skilled workmanship will result on education and training opportunities on these vernacular building systems, contributing to improve the qualifications of the several construction stakeholders, being also crucial for policymakers (e.g., politicians, sociologists and economists) who take decisions about the built environment (Oliver, 2006). In terms of creating a healthy indoor environment, these materials have low

toxicity, no volatile organic compounds and, some of them, have properties that contribute to regulating the temperature and indoor air quality (Berge, 2009), as referred in the example of earthen architecture. In terms of economy, Goodman (Berge, 2009) argues that an industry of ecological construction must have their production units near the place of consumption, using local renewable resources, focusing on processes that require little energy and produce reduced pollution. In order to promote and implement this goal, it is necessary to involve the local authorities. Each side has its own idiosyncrasies that must be taken into consideration in the definition of specific policies adapted to the different contexts (Dumreicher and Kolb, 2008). Supporting sustainable local development means also preserving the cultural heritage of construction knowledge that is characteristic of a certain region.

Nowadays, the interest in vernacular materials is rising in the construction sector, and slowly they are being reintroduced again in the design of buildings, through an optimised combination between the knowledge of the past with the current scientific and technological developments. In this sense, this study presents an environmental LCA of two earthen building techniques: the rammed earth, a technique that was widely used in the past in Southern Portugal; and the compressed earth block (CEB), which can be considered a technical evolution of the vernacular construction material adobe. The LCA is based on specific life cycle inventory data of the product stage of these two building materials. The specific data is from a company located in Alentejo, a region in the South of Portugal.

Use of Rammed Earth and Compressed Earth Block in Portuguese Building Construction

In the past, in Portugal, the materials used for building construction were obtained from the geographical area of the construction site. The industrialisation promoted the use of industrially-produced materials, which are normally produced very far away from the construction site, implying the transportation for long distances and the related potential environmental impacts. Due to the industrialisation, from the beginning of the twentieth century to a recent past, the use of traditional materials and techniques was very limited and an important part of the associated knowledge was lost.

Portugal is a small country, but it is full of contrasts in climate, with significant variations in air temperature and precipitation and in lithology. In Portuguese vernacular architecture, it is particularly evident that there is an almost perfect correlation between the distribution of the building materials used and the lithological characteristics of Portuguese territory (Fernandes *et al.*, 2015b) and one of these materials is earth.

The rammed earth is a building technique that consists of infilling a formwork with soil with a wet consistency that is then compacted in layers. Rammed earth is still now the most prevalent construction technique in existing buildings of the Alentejo region. In this region, the good quality of soil for this type of construction technique is the main justification for its wide use (Fernandes *et al.*, 2015a). Buildings with rammed earth walls have high thermal inertia, which allows them to respond appropriately to the scorching summer heat of Alentejo.

The compressed earth block (CEB) is a technical evolution of the adobe blocks and is obtained by manually or mechanically compressing the earth within a formwork. These blocks can be done only with earth or contain additives to achieve better mechanical performance. Since the earth is compacted directly in the formwork, the blocks can have different shapes, ranging from massive to perforated. The use of earth in architecture continues to make sense in the Portuguese context, due to its several advantages (Fernandes *et al.*, 2015b): strong thermal inertia; ability to influence the quality of indoor air; hygroscopic inertia, contributing to regulate the indoor relative humidity; low embodied energy; low potential cradle-to-grave environmental impact; low-cost material; and at the end of the lifetime it can be recycled and used again in a new life cycle. Buildings made with earth have great durability, since there are a lot of examples with hundreds of years old, and some with a lifetime over than one thousand years, which are still in operation. Although this construction system needs some periodic maintenance, the interventions are normally low cost. Despite these materials have some advantages compared to conventionally used building materials, some of their functional properties, as for instance the thermal insulation, can still be improved. Pereira and Correia da Silva (2012) reported the possibility of improving the thermal insulation of rammed earth walls, in order to comply with the Portuguese regulation on thermal performance, without changing their environmental characteristics, by adding granulated cork in the soil mixture.

Materials and Methods

The Life Cycle Assessment (LCA) of rammed earth and compressed earth blocks (CEB) is based on the specific life cycle inventory data provided by a Portuguese company located in the south of the country. The used method complies with the standards ISO 14040, ISO 14044 and EN 15804.

Functional Unit and System Boundaries

In this study, the objects of analysis are rammed earth and CEB. The declared functional unit is dependent on the goal of the life cycle analysis and in this case the impacts resulting from the production of 1 m³ of rammed earth and 1 block of compressed earth

Fig. 1 Diagram of the manufacturing processes of compressed earth block (CEB).

blocks are estimated. This will allow comparisons with other building materials. The boundaries of this work consider the embodied (cradle-to-gate) environmental impacts of the two studied materials. This means that the study takes into account the impacts resulting from the extraction of raw materials, production of secondary products produced by other companies, transportation of the materials to the facility and manufacturing processes. **Figs. 1** and **2** present, in a simplified way, the processes that were included in the LCA analysis and the boundaries of the study.

Inventory Analysis

To quantify the environmental indicators it is necessary to first develop the inventory analysis (Teixeira *et al.*, 2016). The inventory is used to quantify the inputs (e.g., energy, raw materials and chemicals) and the outputs (e.g., emissions and wastes) of the product system.

Data used for the modulation of input and output flows of energy and mass is based on a quantitative and qualitative analysis of information received from the manufacturer and of technical documentation of the mechanical and electric equipment used. Generic data was used for the processes in which the manufacturer does not have direct influence or specific information. Therefore, generic data from the Ecoinvent v3.3 database were used for the production of fuels, electricity, tap water, hydrated lime, packaging plastic, wooden pallets and transportation processes. The following processes are excluded from this study: (i) environmental loads resulting from the construction of industrial infrastructures and production of used equipment; and (ii) environmental loads related to the transportation infrastructures of pre-products (e.g., production and maintenance of vehicles and production and maintenance of roads).

The life cycle of the two products was modulated using the SimaPro v.8.4.0 software. Since this study is focused on the analysis of two environmental indicators (Global Warming Potential – GWP and the Total Embodied Energy – EE, tot), the following two lifecycle impact assessment methods were used, respectively: CML-IA v.3.4 method and Cumulative Energy Demand v.1.9 method.

Results and Discussion

Table 1 presents the results from the quantification of the potential environmental impacts related to the production of 1 block of CEB and 1 m³ of rammed earth and the contribution of different information modules of the product life cycle stage: A1 – raw materials supply; A2 – transportation; and A3 – manufacturing. Since the rammed earth is only materialized in the construction site, the construction process stage was also included. Therefore, the transportation of materials and equipment (information module A4) and the construction process (A5) were considered in the life cycle analysis of rammed earth.

Fig. 2 Diagram of the manufacturing processes of rammed earth.

Table 1 GWP and EE, tot related to the product life cycle stage of 1 m³ of rammed earth and 1 block of CEB

Information modules of the product stage	Rammed earth (1 m ³)		CEB (1 block)	
	GWP (kg CO ₂ eq)	EE, tot (MJ)	GWP (kg CO ₂ eq)	EE, tot (MJ)
A1	3.14	48.84	0.02	0.26
A2/(A2 + A4, in the case of rammed earth)	2.89	48.30	0.11	1.74
A3/(A3 + A5, in the case of rammed earth)	44.26	529.04	0.26	1.93
Total	50.28	626.18	0.39	3.94

Analysing the results it is possible to conclude that the manufacturing stage is the one that most contributes to the environmental impacts of both materials. Additionally, the production of CEB has higher potential environmental impacts than the production of 1 m³ of rammed earth. This is mainly due to the higher impacts resulting from the transportation and manufacturing stages of this material and could be minimised if the production of CEB was done in the same place of earth extraction/preparation, which is the case in the rammed earth.

In order to understand if these two materials have a good environmental performance, it is also necessary to compare these results with the ones of conventionally used building materials. In this case, the results were compared with the ones of the ceramic brick, the most used material in Portugal to build walls and the declared functional unit is 1 kg. In the calculation of the potential environmental impacts of the ceramic brick, the generic LCI data from Ecoinvent v3.3 database and the transportation distance from the nearest brick manufacturer were considered.

Fig. 3 presents the cradle-to-gate environmental impacts resulting from the production of 1 kg of each material. The differences between the three materials are similar for the two environmental impact parameters, being the rammed earth the one that presented the lowest values. Additionally, both earthen materials have substantially lower potential environmental impacts than brick.

Nevertheless, it is important to highlight that the comparison presented in **Fig. 3** is based on the same amount (1 kg) of material, but when they are used in the construction, different kilograms of each material are necessary to satisfy the same function. Therefore, it is necessary to compare these three materials when they are used to fulfil the same function. In the case of this study, the comparison is made considering the amount of material that is needed to build 1 m² of common walls. Six alternatives for walls were considered: 15 cm thick CEB wall with and without plaster since CEB does not need plaster to be finished; 60 cm thick rammed earth wall without plaster; 22 cm thick hollow brick wall finished with plaster in both surfaces; and

Fig. 3 *GWP and EE, tot* related to the product life cycle stage of 1 kg of CEB, rammed earth and ceramic brick.

Fig. 4 *GWP and EE, tot* for 1 m² of each alternative wall.

15 cm thick reinforced concrete wall. The considered plaster is the same for the different walls and is made with Portland cement. In the calculation of the potential environmental impacts of the ceramic brick, cement mortar, concrete and reinforced steel, generic LCI data from Ecoinvent v3.3 database and the transportation distances from the nearest producers were considered.

Fig. 4 presents for the six alternative walls mentioned before the values of the two impact categories. It can be observed that the CEB wall without plaster presented the lowest values for both impact categories. One interesting observation is that when the comparison is made at the scale of the building element, CEB is the material with the lowest potential environmental impact, but when comparing 1 kg of each material, the best material is the rammed earth. This is because the weight of CEB needed to build 1 m² of wall is much lower than the weight of a rammed earth wall.

Conclusions

The life cycle assessment results presented in this study are based on specific data from a Portuguese manufacturer of earthen materials (compressed earth blocks – CEB and rammed earth) and showed the substantial environmental savings resulting from the use of these materials in comparison to the use of ceramic brick and reinforced concrete. The comparisons are made at the level of 1 kg of material and also for 1 m² of an equivalent wall, considering the cradle-to-gate life cycle stages. Although the end-of-life impacts are not considered in this study, it is necessary to highlight that earthen materials would also have lower potential environmental impact in that stage, compared to ceramic bricks and concrete, since they can be easily recycled to be used in the production of new earthen materials or they can be simply disaggregated and returned to the natural environment at an insignificant environmental impact.

In the case of the compressed earth block there are two major contributors to the value of the analysed environmental parameters: (i) the transportation of raw materials (soil mixture from the extraction site to the manufacturing site and hydraulic lime from the producer to the manufacturing site); (ii) and the manufacturing process of the block, mainly due to the electricity and fuel consumption in the soil sieving, mixing and pressing processes. For the rammed earth, the major contributor is the manufacturing process, mainly due to the fuel consumed in the mechanical ramming process. The potential impacts of the CEB would be lower if the production facility was closer to the place where the extraction of soil is made.

Results of this study show that the two studied vernacular materials have substantially lower environmental impacts when compared to the equivalent materials that are currently used today in the construction sector. Vernacular materials are locally available and therefore they do not need to be transported for long distances. Additionally, they need very low intensive energy manufacturing processes and therefore they have lower embodied energy than conventional building materials. From the analysis of the results, it is evident that the use of the two earthen materials can contribute to decreasing the embodied impacts of a building, but further studies are needed in order to consider other life cycle stages, such as the use stage.

Thus, to achieve the goals for a more sustainable built environment, architecture and construction industry should seek an optimised integration between tradition and modernity, using the best of both at the level of know-how, techniques and materials. Beyond the environmental issues, promoting the use of local materials may have a positive impact on the local social and economic developments. It is up to designers to use their creativity to improve and adapt these vernacular techniques to the new functional requirements. Nevertheless, internationally there is still a lack of quantitative information of most of vernacular materials and techniques. Therefore, more studies are needed to analyse and identify the best vernacular techniques and materials so that they can be improved and scientifically validated in light of the actual technological and scientific knowledge. This will give credibility to those materials and will promote their use by the different stakeholders of the building sector.

Acknowledgements

The authors would like to acknowledge the support granted by the FEDER funds through the Competitivity and Internationalization Operational Programme (POCI) and by national funds through FCT – Foundation for Science and Technology within the scope of the project with the reference POCI-01-0145-FEDER-029328, and of the PhD grant with the reference PD/BD/113641/2015, that were fundamental for the development of this study. The authors also wish to thank the construction company for providing the life cycle inventory data and supporting this research work.

Background and Context

India is urbanising at a rapid pace and is projected to add 416 million new urban dwellers by 2050 (UN DESA, 2018). The majority of this is attributed to the growing rate of rural to urban migration, which in turn has rendered stress on the existing basic amenities and infrastructure. According to a recent estimate by the Ministry of Housing and Urban Affairs (MoHUA), the total urban housing shortage at the end of 2017 was about 10 million, with majority of this pertaining to the houses for the Economically Weaker Sections (EWS) and Low-Income Groups (LIG) (PIB Gov. of India MoHUA, 2017). Through its “Housing for All by 2022” mission, the Government of India intends to close this gap by aiming to construct 12 million housing units over the programme duration (2015–2022) through a combination of slum upgradation projects in partnership with the private sector, direct government-led housing delivery, a credit-linked subsidy scheme as well as support to beneficiary-led construction (MoHUA, Govt. of India, 2017). However, such a focus has multiple implications.

First, housing construction must factor in the environmental risks embedded in its processes. For example, increase in building construction is associated with a rise in energy consumption at an annual rate of 9% compared to the increase in overall national energy consumption of 4.3% (UN-Habitat, 2015a). Residential construction consists of the largest portion of this growth (AEEE, 2015). Continued energy consumption in an inefficient manner runs the risk of increased greenhouse gas emissions. Furthermore, the demand for raw materials, such as sand and soil, are expected to grow as construction rises. This can increase the risk of land and riparian degradation. Given the criticality of such resources in sustaining other sectors such as agriculture, increased competition can cause social conflict (Caleb *et al.*, 2017).

Second, the speed at which housing is to be delivered must not only prioritize the provision of shelter at affordable rates, but also incorporate the adequacy of a home as well as the international Human Right to Adequate Housing, and include its seven criteria: tenure security, affordability, habitability, availability of services, accessibility, location, and cultural adequacy. This means housing policies and construction practices should account for multiple factors, including, *inter alia*, and access to basic facilities, infrastructure, and employment opportunities (UN-Habitat, 2017). Poor access to adequate housing is associated with several measures of well-being such as health and chronic poverty (UN-Habitat, 2015b).

Third, housing construction should harness the job creation potential of the construction sector. In 2013–2014, the real estate sector contributed to 6.3% of GDP and employed approximately 7.6 million people (Gopalan and Venkataraman, 2015). The sector's output value is expected to grow at a compound annual growth rate (CAGR) of 4.16% for the 2017–2021 period compared to 3.95% between 2012 and 2016 (Global Data, 2017). These projections are promising. However, rapid housing delivery may also involve utilization of less labor intensive, and more mechanized, and efficient building systems for construction. Neglecting the sector's potential could deepen the country's ongoing challenges with meeting the employment needs of the country's burgeoning youth population.

Furthermore, there is India's commitment at the global level regarding mitigating climate change and resource efficiency in particular. Also, under the 2030 Agenda for Sustainable Development that proposed 17 Sustainable Development Goals, Goal 11: Make cities and human settlements inclusive, safe, resilient and sustainable and Goal 12: Ensure sustainable consumption and production patterns - particularly focus on the impacts of the rapid pace of urbanization and growth in the construction sector. While the Government of India has allocated tremendous resources to ‘ensure access for all to adequate, safe and affordable housing and basic services and upgrade slums, by 2030’ (Goal 11-target 11.1), the delivery of less sustainable housing still represents a challenge to other sustainability dimensions. Although there is increasing knowledge about sustainable development in India, sustainability is yet to become mainstream in housing construction, evident by the limited uptake of alternative construction materials that are environment friendly and cost effective.

Given this context, the “Mainstreaming Sustainable Social Housing in India project (MaS-SHIP)” was designed to build upon work previously undertaken in the field of sustainable social housing globally and India in particular, while recognizing the priorities set by the Government of India, as well as their inherent constraints. In India, social housing is a rarely used term (Herda *et al.*, 2017). Instead, government and the private sector typically use affordable housing to frame housing policy and practice. However, this term can be applied to any income group whereas social housing applies to a country's most economically vulnerable section.

This study was framed within the parameters of social housing because it focused on India's poorest segments – the Economically Weaker Segments (EWSs) and Low Income Groups (LIGs) (Fig. 1) – because the majority of the country's housing shortage, estimated to be between 10 million (MoHUA, 2017) to 12 million units (FSG, 2018), is concentrated amongst such

Fig. 1 Social housing definitions as implied by the research.

Fig. 2 Attributes selection process.

segments. The study was designed to integrate sustainability in social housing projects in India through the adoption of sustainable building materials and systems, as well as design and management practices by:

- Identifying and selecting a set of 'attributes' to define the sustainability performance of 'established' and 'emerging' building materials and systems for social housing projects, in consensus with experts.
- Developing and testing interactive tools to enable developers, practitioners and policy-makers make informed decisions about integrating sustainability in the design and specification of building systems in social housing projects.

Methodological Approach

The study adopted a socio-technical approach bringing together lessons from previous research, stakeholder engagement methods, with field surveys and statistical analysis. A review of literature helped to define the extent and scale of challenges and opportunities for mainstreaming sustainability in social housing in India. It also helped to identify a list of established and emerging building materials and systems appropriate for the social housing sector, as well as attributes to assess their sustainability performance in terms of environment, resource efficiency, user experience and economic impact. The methodological approach is shown in [Fig. 2](#).

Fig. 3 Level of participation at MaS-SHIP stakeholder events by different types of organizations.

Literature Review

An extensive review of relevant literature (policy documents, journal articles, reports) was conducted to analyze the problem of (social) housing shortage and provision in India, along with the Government's response at the national and state level. National and international case studies of social housing projects were used to derive learning that could positively influence the Government of India's prerogative to provide housing for all. The literature review helped to gather background evidence about policy drivers (and barriers) for integrating sustainability into low-income housing and the development of tools to help in making such decisions. It also informed the selection of attributes to evaluate sustainability performance of selected building materials and systems.

Stakeholder Workshops

Stakeholder engagement through workshops formed a key research tool to gather collective opinions from experts during the course of the study. These events allowed an interactive exchange between the MaS-SHIP team, and various experts associated with the housing and sustainability sector. A total of eight stakeholder engagement workshops were held in three different cities in India at various stages of the study that led to engagement with 112 organizations that included policy-makers, academics, housing developers (public and private), building material manufacturers, architects, building consultants and the voluntary sector. Various organizations from voluntary sector working towards promoting sustainable practices in the Indian construction industry were also well-represented (Fig. 3).

Surveys

In order to address the data gaps, primary data were gathered using interview-based questionnaire surveys to enumerate the qualitative and quantitative sustainability attributes of the selected building systems. Stakeholders included building practitioners (architects, consultants); building material manufacturers and social housing residents. An online survey of experts was also conducted to establish the relative weightings of the selected attributes of sustainability.

Online survey: In order to assign relative weightings to selected attributes of sustainability, the research team conducted an online survey of experts relevant to the housing and sustainability sector in India. The respondents provided weightings to the selected attributes according to their preference or relative importance given to an attribute while selecting building materials and systems for any housing project. The survey was designed based on the Analytic Hierarchy Process (AHP). A total of about 200 responses were gathered, the statistical analysis of which allowed the research team to establish the relative weighting of the selected attributes. The three survey forms are available within the DST that is accessible on the MaS-SHIP website.

Selecting Sustainability Attributes

A key aspect of MaS-SHIP research was to systematically select relevant attributes that can be used for characterising the sustainability performance of building materials and systems. This enabled a comparative evaluation for their application in social housing projects. The literature review along with deliberations with experts during the MaS-SHIP stakeholder engagement workshops enabled the development of the selected 18 attributes. The multistep approach led to progressive iterations to reach the final set of 18 attributes (Fig. 4) that holistically defined the sustainability character of the building material and systems being evaluated.

Their units of measurement were finalized for indicating sustainability, and categorized under four main-criteria namely:

- *Resource Efficiency*: to comprehensively account for the energy consumed and resources extracted throughout the entire life cycle of the construction process.
- *Operational Performance*: to factor in traditional efficiency metrics to ensure high quality building construction.
- *User Experience*: to factor in the role of residents and building practitioners in terms of their familiarity and experiences with existing options and sustainable alternatives.
- *Economic Impacts*: to link better environmental choices with a comprehensive set of economic indicators, including cost and job creation potential.

The list of all the selected attributes along with their description and units of measurements is available in the Annex.

Assigning Relative Weightings to the Attributes

To avoid any bias towards an attribute, it was necessary to assess the attributes with respect to each other rather than assigning equal weightings. This helped to establish the relative importance or preference for the 18 attributes. To assign weightings to the attributes, a survey based on Multi-Criteria Decision Making (MCDM) system was designed to evaluate the attributes with respect to each other. The mathematical technique finalized for MCDM was Analytical Hierarchy Process (AHP), which was selected to assign relative weightings to the selected attributes.

An online nationwide survey based on the AHP technique was conducted to evaluate the relative importance of the 18 attributes. The selection and finalization of the survey design was primarily done by reviewing similar AHP studies. Based on the rankings given by the experts as per the study, the following design was finalized (Table 1).

Fig. 4 Final list of attributes.

Table 1 Defining the nominal ratio scale for the AHP survey

Attribute	Left side scale				Center	Right side scale				Attribute
	Very high effect	High effect	Moderate effect	Slight effect		Slight effect	Moderate effect	High effect	Very high effect	
A	9	7	5	3	1	3	5	7	9	B

Note: If A has higher effect, use left side of the scale.

If both, A and B have equal effect, the center of the scale is to be selected.

If B has higher effect, use right side of the scale.

**Fig. 5** Different user groups for the AHP survey.

The nominal ratio scale of 1–9 (Saaty, 1990) was adopted for doing the pairwise comparisons. The formulated decision hierarchy and the above design were then tested through different MaS-SHIP stakeholder events and subsequently improved. The final decision hierarchy comprised of the four main criteria: Resource efficiency, Operational performance, User acceptability and Economic impacts. Pairwise comparison of the attributes grouped under each main criterion was followed by pairwise comparison of all the four main criteria with each other. The final decision hierarchy was the basis on which the attributes and criteria were compared for evaluating final weightings.

The Analytic Hierarchy Process is one of the pre-eminent approaches for formal decision-making techniques. It is critical to select the correct data sample size which is required for a comparative analysis to provide tangible results. The key to arriving at a statistically valid result is finalizing an appropriate sample size.

Determining Sample Size

There is no limitation on the population size that one can take up for a survey. Also, the greater number of different user groups that are represented in the survey, the better it is. For the MaS-SHIP AHP survey the different user groups are shown in Fig. 5. In response to the MaS-SHIP survey, it was imperative to select the representative sample size as this would then become the population set and sampling of the responses would become a key parameter of the analysis to remove any biases from the survey results.

Fig. 6 User groups of respondents.

Targeting the Representative Sample Size From the Population

Selecting the representative sample out of the population set is of utmost importance and various factors such as respondent's age, experience in sustainability, profession, qualification etc., had to be considered while sampling the responses received from the AHP Survey. To avoid any skewed results that may occur during sampling the responses, a Stratified Random Sampling process was adopted where the sampling frame was divided into smaller sub groups. Thereafter, the groups were stratified based on the relevant years of experience in sustainability.

Confidence Level and Confidence Interval

Once the required sample size was arrived at, finalizing the required confidence level of the survey and the confidence interval was essential. The confidence level is expressed as a percentage and represents how often the true percentage of the population who would pick an answer lies within the confidence interval. The confidence interval is also called margin of error.

The margin of error in a survey is approximately equal to the inverse of the square root of the sample size. However, a margin of error more than 10% is not recommended while conducting the surveys. The MaS-SHIP AHP surveys targeted an error margin in between 5%–10%. This implied that a sample of 100–400 responses was desired.

Expert Survey Results

The survey helped in establishing relative weightings of the 18 attributes comprising the Sustainability Assessment Tool (SAT). A total of 200 responses were received from leading experts in the building industry across India. All 200 responses were checked for consistency and the weightings for the attributes were eventually derived from the consistent responses of 184 experts. The 184 consistent survey respondents were categorized into user groups as per their area of expertise (**Fig. 6**).

About 108 respondents out of the 184 belonged to the project consultant group contributing to nearly 59% of the responses. The respondents were also assessed in terms of their experience in the field of housing sector and/or sustainability (**Fig. 7**). The research team assessed the difference in responses of the respondents having 0–2 years (56) of experience in sustainability as opposed to the ones with experience of 3 years (52) and above. Since there were no significant disparities observed in the responses of both groups, the MaS-SHIP team decided to use all 184 responses to evaluate final weightings of the attributes.

Based on the analysis of the survey results, weightings were obtained for the 18 attributes (**Fig. 8**). It was evident from the AHP survey that each respondent group had their bias towards certain attributes. As expected, the private housing providers preferred 'construction cost' over all other attributes. However, it was encouraging to note that attributes such as 'familiarity', and 'modification ability' were also highly preferred. These results were no different from the overall weightings of the attributes evaluated.

Even though residents of social housing were not a part of this expert survey, it was interesting to find that attributes affecting them such as 'familiarity', and 'modification ability', came second in terms of preference, after 'construction cost'. 'Impact on cooling (or heating) loads' was also among the most preferred attributes.

It was evident that the performance of building materials and systems against the most preferred attributes namely 'construction cost', 'familiarity', 'modification ability' and 'Impact on cooling (or heating) loads' would have maximum impact on their final scores.

Fig. 7 Experience (in years) of the survey respondents.

Fig. 8 Final weightings of the 18 attributes.

Decision Support Toolkit (DST)

The data and knowledge assimilated in the study was brought together in the form of a web-based Decision Support Toolkit (DST) with embedded tools, to enable practitioners, housing developers and policy-makers for integrating sustainability concepts in the planning, design and selection of building systems in social housing projects. The Decision Support Toolkit (DST) is an interactive web-based toolkit that not only helps to bring together the outputs and insights from the research, but also provides a unique platform in the social housing sector with data and knowledge on various aspects of sustainable (social) housing. The DST is developed with an aim to enable developers, practitioners and policy-makers to integrate sustainability concepts in the planning, design and specification of social housing projects in India.

Fig. 9 Snapshot of decision support toolkit (DST).

The web-based DST (**Fig. 9**) was designed to address the requirements of different stakeholders involved in the social housing sector. It was organized around the following key themes to maximize engagement with different stakeholders:

Why should sustainability be integrated in social housing projects?

Before delving into ways of incorporating sustainability measures in housing, the DST helps the user understand why this should be done. This section helps the users of the toolkit to familiarize themselves with the social housing sector through its realities today, national policy scenario, best practice examples and opportunities for sustainability in the Indian housing sector.

How should sustainability be integrated into the design of social housing across different climatic zones in India?

The practice of sustainability is still at an early stage in the Indian housing sector. The most efficient way for achieving sustainability is to incorporate its principles in the planning and design stage of the project. There is information available to guide practitioners in this aspect, but this is largely fragmented and available in different versions pertaining to different sources. This section of the toolkit collates the principal design guidelines for sustainable housing in five climatic zones in India. These guidelines drawn from existing literature in the Indian context such as the National Building Code of India (NBC), Design guidelines for Multi-storeyed residential buildings developed by BEEP India and various similar works, data collected in the study as well as findings from the resident's experiences gathered from surveys of housing projects. The guidelines provide an overview of different aspects to be addressed at project conception stage, including passive design strategies, material use and its impact on energy consumption for indoor comfort, maintenance and up-keep of the site and water conservation measures. The guidelines though brief, serve the purpose of directing the user's thoughts towards different aspects and ways of integrating sustainability in social housing projects.

What sustainable building materials and systems are appropriate for social housing projects? What criteria should be used to evaluate their performance?

This section is the core part of the DST and brings together all data collected on building materials and systems which can be considered for social housing. The data for each building system is organized as pertaining to a set of attributes identified and defined by the study. This is intended to assist the user in making an informed choice of building materials and systems by evaluating their sustainability through multiple criteria. The following information is available in this section:

- Sustainability attributes for evaluating building materials and systems,
- Seventeen catalogs for building materials and systems providing data on their performance against the framework of 18 sustainability attributes,
- Analysis of comparative performance of these building systems with respect to sustainability,
- A User guide to using the Sustainability Assessment Tool (SAT),
- The Sustainability Assessment Tool.

Fig. 10 SAT embedded in the DST.

Where are these sustainable building materials available?

The construction sector in India is very diverse and unorganized in nature. About 98% of the construction companies are small and medium scale enterprises. Unlike the manufacturing industry, it is not always repetitive and is project specific and dependent on the source of the local material. A key aspect which governs selection of building materials and systems is transportation distance for delivering materials to construction site and the associated transportation cost. This section provides a guide to the user to locate existing building material manufacturers across the country, with basic information given on each manufacturer for ease of communication. Thus, the user can make an informed decision on the choice of material or system to be used, based on the estimated distance and scale of supply of the manufacturing unit to the proposed construction site.

Also given in this section are formats for recording basic information about building material/system and for specific details of a social housing project. This is to enable the addition of new materials to the DST and to the GIS-based database to maintain the dynamic nature

Who are the residents of social housing and what are their experiences of living in such developments?

This section provides the users, access to the findings from the case study of the five social housing developments in different climatic zones. The case studies are based on surveys of 723 residents belonging to the five housing developments. The resident surveys gather user experience with indoor environment (air temperature, air quality, air movement, overall experience), natural light, problems of dampness, quality of construction and accessibility to amenities.

Sustainability Assessment Tool (SAT)

The Sustainability Assessment Tool (SAT) is one of the key components of DST (Fig. 10) and was developed using a Multi-Criteria Decision Making (MCDM) method to enable developers and designers make informed decisions regarding the selection of building materials and systems for walling and roofing, for deploying in social housing projects in India. Currently, SAT evaluates 12 established and 5 emerging building materials and systems against the 18 attributes. It is an easy-to-use, interactive excel tool that is available through the DST. Presently a beta version of the tool has been developed which can be reviewed, tested and modified progressively.

This section describes the development and potential application of SAT using the results of the AHP survey conducted among 200 experts. This was combined with the data gathered for the 17 building systems against each of the 18 attributes.

Methodology underpinning SAT

Given the difference in the nature of the data gathered against the 18 attributes (qualitative and quantitative), their units of measurements and gaps in the data, it was important to select a methodology that would capacitate both qualitative and quantitative datasets and cater for data gaps while evaluating building systems. All the attributes and the building materials and systems had to be assessed on a level plane to achieve precise scores.

Resource Efficiency				
Attributes	1. Embodied energy and carbon emission	2. Critical Resource use	3. Current recycled content	4. Future reu:
Evaluation scale	MJ/Sq. M	High-Medium-Low	%	High-Medium
Evaluate - Yes/No	No	No	No	No
	Yes No			

Fig. 11 Selection of attributes to evaluate the building materials and systems.

The Multi Criteria Decision Making (MCDM) approach was selected to bring together the quantitative and qualitative data to derive the relative weightings of the attributes for each of the 17 building systems. The approach and methodology were developed so that they provide tangible outcomes and trade-offs as a measure of sustainability.

An extensive literature review was carried out to identify a Multi Criteria Decision Making (MCDM) method which would address all the above challenges to give credible results. MCDM methods such as Analytic Hierarchy Process (AHP), Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS), Multi-Attribute Utility Theory (MAUT), Preference Ranking Organization METHod for Enrichment Evaluation (PROMETHEE) and Weighted Sum Model (WSM) were studied. While some of these could help in overcoming the above challenge, most of them were unable to address the issue of missing data under different attributes.

The MCDM problem considered at the building material and system level in SAT was categorized as a non-classical MCDM problem as it accounts for the missing data under the attributes. The non-classical MCDM method used in SAT is Belief Function based TOPSIS. The Analytic Hierarchy Process (AHP) was selected as the MCDM method to evaluate the attributes and as a result, relative weightings were ascribed to them, to determine the order of preference at criteria level. The data collected for the 17 building materials and systems against the 18 attributes defined the problem statement to select a suitable method for evaluating them under the existing challenges.

The proposed Belief Function based TOPSIS was classified as MCDM tool (Dezert *et al.*, 2016) as its purpose is to help the 'user' to choose a building material or systems among a known set of 17 based on their numerical scores calculated with respect to data collected under 18 attributes.

This new approach offered the advantage to deal directly with negative, zero and positive data values, missing data values, and unreliable sources of information related to each attribute as well. This process assigned belief, plausibility and uncertainty for the missing data values to which TOPSIS was applied subsequently to obtain final scores of the building materials and systems.

Although this MCDM problem was easily formulated, there were difficulties in solving it because the data under various attributes was expressed in different units and scales. Such differences in the unit and scale of data gathered necessitated a normalization step that could have yielded further problems like rank reversal. A rank reversal is a change in rank ordering due to addition or deletion of a building material or systems from the list.

The process for developing SAT calculations involved creating a 'base matrix' comprising of 18 attributes with data populated for 17 building systems. The matrix had both qualitative and quantitative sets of data. The missing values in the matrix were denoted by 'NA'. These missing values were addressed by adopting a theory of belief functions or the Dempster Shafer's Theory which involves assigning probabilistic values of belief, plausibility and uncertainty to data values. After calculating the belief, plausibility and uncertainty, TOPSIS method is applied to the matrix to arrive at the final scores of the building systems.

Interpretation of SAT scores

The SAT enables the user to make an informed choice by providing the order of preference of the 17 walling and roofing systems against all 18 attributes. The user can select the attribute or attributes grouped under the four main criteria (Resource Efficiency, Operational Performance, User Experience and Economic Impacts) to evaluate a total of 17 walling and roofing systems. The selection can be completed by picking a 'Yes' from the dropdown list placed under each attribute (Fig. 11).

Fig. 12 shows the walling and roofing systems evaluated for the attributes under the criterion 'Resource efficiency'. Higher score of a building material or systems with respect to others is an indicator of its better performance. A high score is better and independent of the nature of the attribute. For instance, a high score of a building material or system for an attribute 'Embodied energy and carbon emissions' indicates that it has a low absolute value (MJ/m^2) which has led to its high score. In simpler terms, the higher the graph spikes, the better the score gets, hence the better the performance. Similarly, results for other criteria (Operational performance, User experience and Economic impacts) can be evaluated using SAT. The holistic score across all or selected attributes is also displayed towards the bottom of the SAT under 'Sustainability Assessment – Holistic' (Fig. 13). A detailed guidance document on 'how-to-use' SAT is available as part of the DST.

While SAT is a novel tool for appraising the performance of building systems against a wide range of attributes, it is important to remember that presently, it provides comparative analysis of 17 selected building systems against the 18 attributes of

Sustainability Assessment Tool - Criteria wise

Fig. 12 Order of preference across all attributes under 'Resource efficiency'.

sustainability identified for housing units only up to four storeys high. Also, SAT does not give absolute data or values for the building systems evaluated by it under 18 attributes. It only provides a score which has been calculated using the absolute data for building systems under weighted attributes. The 'score' calculated for any particular building system against the 18 attributes is the 'relative weighting' of that particular building system against the other 16 building systems listed in SAT.

Discussion: Wider Application of DST

It is clear that DST can function as a common reference point to overcome knowledge gaps pertaining to the widespread application of sustainability in the Indian housing industry. It can help prospective users meet their individual priorities while factoring into their decision making, broader systemic goals when selecting building materials, making housing design decisions, and understanding why it is important to mainstream sustainable social housing. For example, decision makers have lacked an appropriate framework to measure the performance of existing and new building materials against its socio-economic and operational benefits and environmental risks. To address this gap, SAT was developed as part of the DST. The tool consists of four broad criteria, some of which were missing in the various earlier sustainability assessment tools, including resource efficiency, operational performance, user experience and economic impact.

The DST also contributes to filling the current lack of data that has inhibited decision makers from making informed policies and investments related to sustainable construction practices. For example, the SAT is populated with the performance of 17 building materials and systems to compare available options. Lack of available information has also affected the development of the green materials supply chain. To this end, a GIS mapping of materials offers a platform to promote the location and performance of materials that are not widely known.

The limited availability of high quality, educational materials has also inhibited the implementation of sustainable design and construction practices. The DST's climate specific design guidelines help ensure sustainable material selection is grounded in construction practices that strengthen the quality and adequacy of the home.

In addition, the DST's background on the policy context for housing in India provides important insights into the institutional environment within which sustainability can be mainstreamed. Its documentation of resident experience can also help refine policies to better incorporate the preferences and concerns of the consumer.

Users of DST

Mainstreaming sustainable social housing will require a coordinated effort from multiple actors who may have individual and sometimes, conflicting priorities. What is common among most construction stakeholders is that they lack an

Fig. 13 Holistic sustainability assessment of the given building system using SAT.

appreciation for the concept of sustainable social housing. As consumer preferences and building standards and rules evolve to mandate adoption of more sustainable building materials, social housing developers will need to adjust their practices accordingly.

In this context, the DST can assist developers in calculating the costs of sustainable alternatives and locate the requisite suppliers. As such, the DST could conceivably help capital constrained developers efficiently manage costs and adhere to sustainability criteria. By extension, the tool could be used by developers to promote their commitment to high sustainability standards. In addition, materials manufacturers and suppliers could leverage the materials map to promote their products, form linkages with prospective clients and strengthen the supply chain.

Building practitioners could also benefit from the DST in terms of making incremental, but important, improvements to their design practices. This, in turn would enhance resident comfort. Given that many practitioners train their workers on site, with no consistent approach, the DST could also enable a more systemic way of monitoring workers' performance. This has the potential of realizing construction standards delivered by a largely unskilled cohort of construction workers.

Public sector housing finance and alternative finance institutions, seeking to make impact investments in green, affordable housing, could use the DST to structure their funds. The data on costs and sustainability of various materials can be used to make linkages between returns on investments with socio-economic and environmental impacts.

For universities and students involved in architecture, planning, and civil engineering, DST can function as an important educational tool by establishing an important framework to understand sustainability in social housing. The listing of the attributes can be used by educators as an entry point in developing lessons that explore issues that range from sustainable water practices to supply chain management.

The DST can also potentially assist local government bodies by functioning as a supplementary guide for monitoring and evaluating the quality of buildings. Its free design guidelines, in particular, provide a useful basis for officials with limited technical

resources to make informed decisions. The DST can also be used by state housing agencies planning to incorporate sustainability criteria into procurement guidelines to induce greater adoption of sustainable building materials.

Numerous central government ministries could also find utility in the DST. The potential of the DST in supporting the Building Materials and Technology Promotion Council's (BMTPC) research and promotional endeavors is indicative. For example, the DST could assist in refining the BMTPC's third party "Performance Appraisal Certification Scheme (PACS)". PACS is a voluntary programme that evaluates the performance of emerging materials based on traditional metrics pertaining to cost effectiveness and efficiency. The certified products are promoted to help them gain a foothold in the market. In addition, PACS assist the Central Public Works Department (CPWD) in incorporating findings into its procurement guidelines for building materials. They also support the Bureau of Indian Standards (BIS) such that findings help in reviewing or formulating relevant Indian Standards (BMTPC, 2016). As such, incorporating the DST's evaluation framework could widen the basis of performance and potentially influence codification.

Conclusions and Recommendations

As the Government of India aims to construct 12 million social housing dwelling units through the Housing for All by 2022 programme, the pressure to deliver in a timely and cost-effective way will increase. It is vital to identify what the impacts and benefits of housing production at such a massive scale and speed could be, especially when there is limited evidence of coherent strategies to decouple the socio-economic benefits arising from housing construction and provision from its negative environmental impacts, such as the deleterious effects of resource extraction. In particular, this shortfall applies to how building materials and systems are not selected in a sustainable manner. Research from MaS-SHIP has produced a comprehensive data framework, datasets, tools, evidence-based knowledge and insights for mainstreaming sustainable social housing in India.

A key output from the MaS-SHIP research has been the creation of the DST, an interactive and online toolkit comprising a range of outputs, datasets, tools and insights that can help prospective users in choosing sustainable building materials and making and monitoring sustainable design interventions and construction practices in social housing projects. The DST not only addresses the absence of a comprehensive measurement framework to assess sustainable materials, through the development of SAT it fills missing data that is needed to quantify the performance, and using Material mapping application, spatially maps the availability of sustainable building systems options. DST also includes design guidelines to ensure sustainability is embedded at the conception stage of a housing project. Filling these knowledge gaps can also assist in prioritizing sustainability considerations in housing policy and implementation.

SAT as a key component of the DST has the capability to measure the relative performance of building materials and systems for social housing projects that do not exceed four stories, using the framework of 18 attributes. The multiplicity of attributes requires rationalized valuations relative to each other. SAT establishes consistency by drawing on the inputs of a representative sample of housing experts in India to weigh each attribute. That is, a widely accepted "Analytic Hierarchy Process (AHP)" was applied to survey 200 experts including project consultants, private and public housing providers, academics, manufacturers, and building practitioners. A weighting process affords a rigorous evidence base for prospective users to prioritize their interventions, appropriately allocate resources, and potentially mitigate preconceived biases.

More data is also needed to support initiatives that promote small, sustainable building system companies with a small client base. For example, the Building Materials and Technology Promotion Council (BMTPC), housed within the Ministry of Housing and Urban Affairs (MoHUA) studies and showcases innovative building systems. It is also responsible for a Technology Sub-Mission, which is involved in such pursuits as part of the PMAY. However, the current focus on materials and systems tend to focus on cost and speed. Missing data on criteria such as a building system's job creation potential inhibits systematic efforts to promote such options against broader metrics. Resolving this shortfall could enable evidence based promotional campaigns, to build awareness and induce demand for more sustainable alternatives amongst prospective clients.

Acknowledgment

The MaS-SHIP project has been funded by the Sustainable Building and Construction (SBC) Trust Fund which is one of the means of implementation of the Ten-Year Framework of Programmes on Sustainable Consumption and Production (SCP) Patterns (10YFP) managed by United Nations Environment (UNE). The goal of the SBC programme is to promote resource efficiency, mitigation and adaptation efforts, and the shift to SCP patterns in the buildings and construction sector of developing countries and countries with economies in transition.

Appendix A

See [Table A1](#)

Table A1 Detailing the 18 attributes

Sl. No.	Attribute	What is being measured	Unit	Calculation/Source
1	Embodied Energy and Carbon Emission	It is the total energy expended for implementing a building system, from extraction of material up until the point of installation in a building. This includes energy consumed in: Manufacture of raw material (example-cement, steel); construction/ installation at site; and transportation of materials/ components from manufacturing facility/ material vendor to the construction site.	MJ/m ² of wall or roof assembly	Calculation: Normalized data readily available. Calculations for the embodied energy per m² of wall or roof assembly of each systems have been made in three stages: Raw material → Component → System. Source: Tier 1 level data on embodied energy and emission factors of material on which the calculations for building components and systems are based on.
2	Critical Resource Use	It is the overall impact created critically from the quality of resource usage measured in terms of: A. Scarcity Index: The creation of criticality due to impact on ecology because of the process of extraction of the various raw materials used in the product/building material (e.g., river ecology, forest ecology, mountainous ecology etc.) B. Environmental Impact (soil and water pollution): The degree of water and soil pollution caused during the process of extraction, manufacture and construction. C. Sectorial conflicts/Conflict of use between different sectors: The degree of criticality created due the conflict of use of raw materials in the production of building component or system (e.g., soil is important for food sector, terracotta handicrafts, etc.)	Normalized numeric index Criticality score: Low: 1, Medium: 2, High: 3 The Low-Medium-High ranking refers to severity of the three parameters of Environmental impact, Scarcity and Conflict of use. <i>The rankings are based on a research study conducted by Development Alternatives on Resource Efficiency in the Indian Construction Sector (2015).</i>	Calculation: The calculations have been done using the weights of the critical resources per m² of the wall or roof assembly multiplied by the criticality score of the respective resource. These values are normalized on a 0–100 scale. The formula for calculation can be referred to in the data framework report available from the project website. Source: Weightings given according to Tier 1 data at primary level, with resulting calculations involving T1, T2 and T3 data at assembly level.
3	Current Recycled Content	Quantum of recycled content utilized in the building material which may be achieved by usage of materials which utilize, for instance, industrial waste. The intent is to reduce the dependency on virgin materials such as top soil, sand etc., or on materials with a high environmental impact such as cement.	Scale of High, Medium and Low Low: 0%–20% High: > 40%–100% Medium: 20%–40%	Calculation: Scale derived from percentage of recycled content in the manufacturing of the material. Source: Calculations based on T1 and T3 data, using inputs from manufacturer surveys and prevalent system/ material specifications.
4	Future Reusability	Ability of a material to be used in its second life cycle without any structural changes. The intent is to reduce the generation of C&D (Construction and Demolition) waste at source.	Scale of High, Medium and Low. Low: 0%–20% Medium: 20%–40% High: > 40%–100%	Calculation: The scale has been derived from percentage of constituent materials of the wall/roof, which may be reusable. Source: Tier 3 data from manufacturer surveys and material specifications.

5	Water use (during manufacturing and construction)	Amount of water consumed by building systems including both embodied water content of raw materials as well as process water consumed in production and construction.	Litres per m ²
6	Durability	Time period for which the building material or system is stated to last by its manufacturer under specified conditions of use. Water resistance and compressive strength determine the durability of the material.	Scale of High, Medium and Low
7	Ease and Frequency of Maintenance	Frequency of maintenance works required (regular or occasional). Could involve the following indicators: ● Extra products required for the maintenance ● External help required ● Mandatory frequent services	Scale of High, Medium and Low
8	Thermal Performance (flow of heat)	Thermal performance of a material is a measure of the thermal transmittance (also known as the U-value) which is the property of heat transmission in unit time through unit area of a building material or assembly and the boundary air films, induced by unit temperature difference between the environments on each side. The lower the U-value of a material, the better is its heat insulating capacity.	W/m ² K
9	Thermal Mass (absorption, storage and release of heat)	Thermal mass or thermal admittance quantifies a material's ability to absorb and release heat from a space as the indoor temperature changes through a period of time. In climates with large diurnal swings, admittance values can be a useful tool when assessing heat flows into and out of thermal storage.	kg per m ²
10	Impact on Cooling (or heating) Loads	Impact of the building system used in the construction of any dwelling on the energy consumed for space cooling and/or heating. The intent was to inform the user of the potential savings associated with the use of a building material or system with respect to a specific climatic zone in India.	kWh/m ² /year

Calculation: Calculations are based on embodied water of raw materials, taken according to composition ratios of these materials in the final wall/roof assembly. The final amount includes water for production (on site/off-site) and curing (on-site).

Source: Tier 1 data on embodied water in material have been used as the base for the calculations.

Calculation: Tier 3 data was collected through material catalogs.

Source: Tier 3 data from manufacturer surveys and material specifications.

Calculation: Tier 3 data was collected through material specifications and catalogs regarding the maintenance of the building system. Households were questioned on the ease and frequency of maintenance required in the houses. The scale of high, medium and low comes from the responses of the householders and building practitioners towards these questions.

Source: Tier 3 data from manufacturer surveys and material specifications.

Calculation: Normalized data readily available.

Source: Tier 1 data from published reports and articles, Tier 2 calculations from the CEPT CARBSE Assembly U-factor calculator³, based on the selected walling and roofing assembly

Calculation: The terms heavy-weight, medium-weight and light-weight are often used to describe buildings with different thermal mass strategies.

Source: Tier 1 and Tier 3 data on material specifications, with calculation for change in unit.

Calculation: Simulation based results using DesignBuilder.

Source: Tier – 2 data based on simulations

(Continued)

Table A1 Continued

Sl. No.	Attribute	What is being measured	Unit	Calculation/Source
11	Noise Transmission	Refers to airborne insulation values of walls and airborne and impact insulation values of floors.	Decibel (dB)	Calculation: Normalized data readily available Sound Transmission loss as per IS 1950:1962 30 dB or less – Poor 40 dB – Fair 45 dB – Good 50 dB - Very good 60 dB - Excellent Source: Tier 1 data from published reports and articles.
12	Familiarity (with the material or system)	Degree of inclination towards a building material or system based on user acceptance.	Scale of High, Medium and Low	Calculation: Tier 3 data was collected through household and building practitioner surveys. Household were questioned on their experience with the building system used, while the building practitioners were questioned on their likeliness towards using a certain building system. The scale of high, medium and low comes directly from the responses of the householders and building practitioners towards these questions. Source: Tier 3 data inputs from manufacturer and household surveys.
13	Modification Ability	Suitability of constructed building for adopting changes after construction by occupant, including nail-ability. To be able to make changes like- Concealed piping, electrical, and plumbing services, and provision for incorporating the mechanical, electrical and plumbing services within the proposed building component thickness.	Scale of High, Medium and Low	Calculation: Qualitative tier 3 data was collected through material specifications and catalogs regarding the maintenance of the building system. Households were questioned on the modification ability of the materials used in the structures of the households. Source: Tier 3 data inputs from manufacturer and household surveys.
14	Construction Cost	Cost per m ² of the building system (wall and/or roof). This includes primary material, labor, water and equipment charges. <i>This is not the cost per m² of built up area.</i>	Cost per m ²	Calculation: The cost analysis has been done first through calculation of the cost per component (e.g., solid concrete block) using rates from CPWD's Delhi Schedule of Rates 2016. The cost analysis of the final assembly is done using the above calculated costs of components. Source: Calculation based on combination of Tier 1 data from Delhi Schedule of Rates 2016 and Tier 3 data from practitioners and manufacturers/suppliers.
15	Skill Requirement	Level of skill needed during production and construction of a building material or system.	<20%: Low; 20%–40%: Medium; >40%: High	Calculation: Percentage of skilled personnel required in the construction process. Source: Calculations based on Tier 3 data from practitioners and manufacturers/suppliers.

16	Supply Chain	The availability of number of reliable suppliers for a particular building material or system in the very initial stage of construction of the project and in proximity to the project site.	Scale of High, Medium and Low	Calculation: GIS mapping of building materials and system suppliers Source: Mapping geographic locations of manufacturers and suppliers of building materials and systems (GIS mapping of building materials)
17	Duration of Construction	Time consumed on site in construction, assembly and installation of a building material or system.	m ² of built-up area per day.	Calculation: Tier 3 values from project details, practitioners and developers. Source: Tier 3 values from project details, practitioners and developers.
18	Job creation	Quantum of jobs created per m ² of wall/roof construction in terms of man-days.	Man-days per m ²	Calculation: Man-days per m² have been calculated as a sum of work required per m² of wall/roof assembly by the skilled and unskilled labor in each step of the assembly process. Source: Calculations based on T3 data, values from projects, practitioners and developers.

Evaluation of Sustainability Indicators of Buildings

Anjali K Sharma, School of Planning and Architecture, Delhi, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The development across the globe needs to be sustainable only then the earth shall be a liveable place. Although various efforts are on by each of the nations in their own way to address the issue but isolated approaches shall not yield the desired result unless and until a common platform is drawn up. The developed and developing nations divide is still on and the developing nations are urbanising rapidly and construction of large builtup area is underway. This is inevitable but if not done in a sustainable manner shall have farreaching implications globally. Thus a check and monitoring the same is of utmost importance. Currently, the efforts are on by each of the nations in their own respective ways but if the baselines vary and a holistic approach is missing then the results might be difficult to measure. Therefore resources required for this urban population are important especially from sustainability viewpoint for example, nearly 1.1 billion people had no access to electricity in 2014, and more than 3 billion had no access to clean fuels and technologies. Goal 7 recognizes that extending access to electricity and other forms of energy is fundamental to improving people's lives and communities (SDG, 2018). The numbers are a strong pointer for optimum usage of resources thus the need for evaluation and that too standard as much as possible.

The rating system for evaluation started with BREEAM; UK way back in 1990, with USA initiating LEED in 1998 and Canada, Australia and others followed, while China has adopted few of the existing ones and added on real estate development. Each of the systems has a separate rating system for the building typology and scale. Although most of them address the overall aspects but do have gaps that may be perceived as strongly contextual but has an impact when overall evaluation occurs. The system of evaluation needs to be such that when the buildings are at design stage, few indicators may be addressed, then at detailing stage followed by monitoring when the execution of the project happens and evaluation to continue as Building Performance Evaluation (BPE) over time with room for technology up gradation for appliances and even for the buildings.

The canvas of sustainability indicators is broad-based over rating system of buildings but with time the rating system has evolved to address and quantify the carbon emissions, energy issues with immediate effect however each of the rating system touches upon social and economic aspects in their own limited way often customised. Therefore the need for a system of evaluation of sustainability indicators for buildings need to be in place; to gauge interventions at a global level and for the output to be measured effectively.

Sustainability Indicators

UN developed Sustainability indicators for Sustainable Cities Program (SCP) created in 1992 after the UN Conference on Environment and Development (UNCED), the Commission on Sustainable Development through Agenda 21, included "the implementation of the Earth Summit agreements at the local, national, regional and international levels. Over fifty-five countries experimented the Commission on Sustainable Development program in 1992 each initiative has its own success rate; additionally, as feedback, they put forth some recommendations of indicators to be included in the existing framework. Now fourth implementation cycle on with learning's from the previous cycles the structure is more robust and precise and making it circular in nature.

To arrive at the sustainability indicators for buildings understanding of the said backdrop and the standard UN SDG are a good reference, to begin with and narrows it down for the buildings. List of 17 UN Sustainable Development Goals (Fig. 1), have 232 sustainability indicators, address the said goals, while for buildings only a few are directly applicable. (Is it possible to list down the indicators which directly/indirectly/partially deals with buildings under each UN Goal as listed below?) Of the UN Sustainability Development Goals and their sub-indicators the ones that are related to built environs are goal no: 3, 6, 7, 11, 12, and 13. Considering the rating system tackles few of the sustainability issues based on the rating system at large. The key goals that need to be mapped parallel to rating system are as follows:

Backdrop of Rating Systems of Buildings

To evaluate sustainability indicators for a building, the system needs to be comprehensive in nature as the rating systems validate the building's performance but for it to be sustainable and to be a part of the urban fabric the impact of the building on its immediate surroundings and other related aspects is a concern and needs to be part of the evaluation system as well. Thus a comprehensive understanding of the rating system is documented hereby as follows:

1990 saw BREEAM framed up as BRE – Environmental assessment method started in the UK for new and existing buildings, later that was taken up by other countries as well: Canada, Hong Kong and New Zealand. In 1996 fourteen countries started two year program called it as the green building challenge with the agenda to gauge building performance and energy efficiency by: Austria, Canada, Denmark, Finland, France, Germany, Japan, Netherlands, Norway, Poland, Sweden, Switzerland, United Kingdom and United States and advanced to BEAM – evolved as Building Environmental assessment method. In 1998 LEED – leadership in Energy and Environmental

SUSTAINABILITY INDICATORS FOR BUILDINGS	
UN Goals	UN Goal- Attributes
GOAL 3	Ensure healthy lives and promote well-being for all at all ages. <i>{for Sustainability indicator for Evaluation - The larger context of the goal refers to good health and well being but none of its sub-goals speaks off relating it with productivity; the impact of materials with weathering on the health, that needs attention}</i>
GOAL 6.4	By 2030 substantially increase water -use efficiency all sectors and ensure sustainable withdrawals and supply of freshwater scarcity and substantially reduce the number of people suffering from water scarcity.
GOAL 6.5	By 2030 implement integrated water resource management at all levels including transboundries cooperation as appropriate.
GOAL 6.6	By 2030 protect and restore water related ecosystems including mountains, forests, wetlands, rivers, aquifers and lake.
GOAL 7.1	By 2030 ensure universal access to affordable, reliable and modern energy services.
GOAL 7.2	By 2030 increasingly substantially share of renewable energy in the global energy mix.
GOAL 7.3	By 2030 double the global rate of energy efficiency.
GOAL 11.1	By 2030 ensure access for all adequate, safe and affordable housing and basic services and slums upgrade.
GOAL 11.6	By 2030 Reduce the adverse per capita environmental impacts of cities, including by paying attention to air quality and municipal and other waste management.
GOAL 11.b	By 2020 substantially increase the number of cities and human settlements adopting and implementing integrated policies and plans towards inclusion, resource efficiency and mitigation and adaptation to climate change, resilience to disasters, and develop and implement, inline with the Sendai framework for disaster risk reduction 2015-2030, holistic disaster risk management at all levels.
GOAL 12.2	By 2030 achieve the sustainable management and efficient use of natural resources.
GOAL 12.4	By 2020 achieve the environmentally sound management of chemicals and all wastes throughout their life cycle, in accordance to the agreed international framework, and significantly reduce their release of sir, water and soil in order to minimize their adverse impact on human health and environment.
GOAL 13.1	Strengthen resilience and adaptive capacity to climate related hazards and natural disasters in all countries.

Fig. 1 UN sustainable development goals.

design, 1999 EEWH – Ecology saving. Waste reduction and health, 2000 GREEN GLOBES (Canada), 2002 Green Building certification system and Green Star, 2004 CASBEE (Japan) Comprehensive assessment system for built environment efficiency, 2005 Green mark, Green building standards, 2006 GRIHA (India) Green rating for integrated habitat assessment. With each of the rating system, a dimension has got added from stand-alone building to energy issue to ecology to integrated systems at large. It is meaningful to see the progression in the sustainability indicators from their identification, to recognition to its application.

Technology has shrunk the world and with awareness of rating system the data can be assimilated at various levels till global. Such information shall not only be insightful but shall enable one to take precise measures for sustainable development. Next important initiative is to set up base lines, norms and standards based on geographical, climatic zones with technology aid.

Parallel is the existing building stock that has served for centuries on when the resources were limited and the indigenous technology demonstrates a range of passive systems of which some can be continued even today reducing on the energy demand and ensure the continuity of the traditional architectural styles of the buildings. Conventionally these buildings are looked upon as heritage structures to be valued for its age and architectural style but continuing the time-tested solutions are worthwhile and may be measured for as innovation value too with few modifications if so required with help of technology. Conventionally these buildings are an integral part of the socio-cultural strength of the local population that over time local economies too are dovetailed with them. This inherent balance between the social, economic and the existing built environs proved to be sustainable and therefore are a resource by themselves. Thus it may be noteworthy that the framework of the development of such existing building stock can be evaluated largely for sustainability indicators for buildings as well. Next, the economic dimension of sustainability is seen, limited to buildings only.

Understanding Issues for the Framework of Sustainability Indicators for Buildings

The intent of the paper is to arrive at issues for a standard framework of sustainability indicators for buildings at large. The UN format is universal but the nations are developing across the globe at their own pace. The local negotiations have certain

repercussions as the base line may be common but the thresholds vary with each nation and climate for the people who are the end user of buildings. Therefore this gap/range is significant and needs to acknowledge with reference to socio-economic aspects, as they are key to sustainability.

As building elements are standard for all typologies of buildings that are taken criterion, also tabulating the data shall be faster and even the communication of data for its implications shall be simple to translate irrespective of its geographical location. The vital issues for sustainability indicators of buildings in urban areas are as follows:

- Site and its immediate surroundings – the building to be viewed with respect to its surroundings for planning viewpoint – existing urban tissue, services that may be shared i.e., smart grid/load shifting; mixed land use, response to open spaces, landscape and other design-related decisions.
- Building design – based on typology, architectural style, spans, services-HVAC, Electrical, water, sanitation, waste, security, cost effective with specifications, and most significant the design development stages wherein the rating systems/sustainability concerns are inherent to the design rather than being an add on at a later stage as that gets reflected in the performance at large for it various services that are energy consuming.
- Building materials – selection of materials for foundations, walls, infill walls, all types of fenestrations and roofing as that determines the structural system and need to use of technology. Subsequently the selection of finishes for flooring, walls, service areas and others are crucial as they are a major component of the cost of the building and since it deals with cosmetic aspect of the buildings the options are many and not necessarily environmentally friendly in fact the focus is largely on visual and aesthetics.
- Construction technology and commissioning – implementation of project is typically influenced by the local construction systems at place, use of technology and its related impact. Use of indigenous technology, to handing over to the owner/users and maintenance logistics and data records.

Understanding Evaluation With Rating Systems

The initiative for rating system was taken up by the developed nations first followed by developing nations. When one speaks of sustainability indicators then the three pillars of sustainability are inherent. Having shared the key UN sustainability indicators relevant for buildings an overview of rating system shall enable to put issues in correct perspective for the said agenda of this paper. Each of the rating system are a reflection of the countries where they developed thus for a standard system the regional or local contextual issues also need to be accounted for such along with the socio-economic framework.

To evaluate sustainability indicator of buildings with rating system as well there may appear few gaps that exist may be because of issues, are not contextual/local, regional, political or economic. An attempt to understand the most frequently used rating system and highlighting their respective strengths that are not reflected such in other rating systems but are significant from sustainability viewpoint. Further few issues shared herein are random but directly related to the sustainability aspect for buildings. Beginning with site selection LEED has extensive thrust on natural features, water, and others. While BREEAM has a structured outline for duties and responsibilities during execution of the project and thrust on management is 11% relatively high when compared with other rating systems. Next mixed land use is not recognized by GSAS, GRIHA considering the traditional cities establishes such land use as it reduces on transportation, as production, retail and residence are in same building that demonstrates compact city planning therefore economizing on energy consumption also enjoys inherent social security in the streets they are the life line of the city. Use of transportation is recognized, as 10% by BREEAM while the GRIHA has no mention of that. Globally single residences are large in number but the GSAS have exempted them from the rating system also the noise and light pollution as well. Furthermore they accept the passive systems and recommend them but they are quantified. Use of technology is largely responsible for energy consumption at site during execution of the projects and technology is updated regularly. Often the upgraded technology costs more and efficient as well but among the developing nations there is a tendency to use less upgraded version as that is relatively cheaper but may not be sustainable from environmental viewpoint. Like technology Innovation needs to encouraged as LEED emphasizes a substantially on it to the extent for use of energy modeling technology with versions as well whereas BREEAM gives an over and above credit for the same, rather than being inherent to the rating system. There is ample thrust on energy but no baseline defined by quite among the rating systems. Infrastructure facilities especially HVAC is a major energy consumer over electrical, plumbing, waste, sanitation to mapping of indoor air quality and relating that to productivity, health and well-being is insightful from sustainability point of view. By an large number of users and relating them with defining base line is missing considering although in BPE energy consumption per user is documented but with lack of baselines the data is just another number. Similarly there are other issues as well but an extensive study is beyond the scope of this paper thus the above mentioned text is to enumerate the issues of rating system that are a concern for sustainability indicators of buildings at large.

Issues for the Framework of Sustainability Indicators for Buildings

To arrive at the framework of issues for sustainability indicators for buildings the approach was to draw parallel sustainability indicators with rating systems. The outputs of issues are compiled under three sub categories as common for the buildings followed by the geographical location of the project within the socio-economic framework of the building is as follows:

Common indicators

Common indicators of the *four key issues* of a building are: the building design, architectural vocabulary, construction technology and maintenance and technology up gradation. As the cities with their master plans may govern the site selection and that may not be essentially acknowledging the natural features and resources; as land is a premium and invariably the major component of any project. Ideally the site selection to be considered keeping in mind with socio-economic aspects as well: who the users shall be? number of users? daily costs of travelling? gender connotation? security? earnings to savings? financial viability as social equity rather than befitting a chosen few and others. Although it may not within the purview of the architect but role of planner is significant or else it shall be a built stock neither used nor occupied. There are quite a few such examples in Asian cities and thus one has metropolitan cities with no limitation for extent of the city. So it is important that the building that one builds is integrated within the city's fabric or urban tissue and an asset at large. Furthermore the building to have a symbiotic relation with its immediate surroundings be it open space or built environs such that resources may be shared and is an asset to its location.

- (1) The Building design is key but the rating systems have a framework to account for that with few gaps based on the countries where they are implemented. But during the design development stages the inclusion of issues if monitored could yield improved results. The baselines be defined for the respective geographical zones as thresholds of thermal comfort varies with ethnic groups/communities and recognizing their thresholds such shall ensure optimum use of resources.
- (2) The global architectural vocabulary is cloning the high end of buildings in cities irrespective of the climatic condition creating buildings that are un-necessary for example glass façade buildings are not called for hot and dry climate so by building such the energy demand multiplies; a price that the city pays to have such built environs and adding heat islands, adding carbon emissions, altering the micro climate and related climate impacts.
- (3) Among developing nations majority of the construction sector has labours that are in farming and migrate during non-farming duration, a social phenomenon related to economic activity. Such labour is not formally trained but cheap: this implies that the quantity of material used may be more and execution of the task may not be accurate at the cost of quality and such a setup has been in operation for years and continuing. Also in such a situation the use of technology may be used judiciously and relying more as labour intensive.
- (4) After execution of the project at handing over stage is formal as maintenance, facility management with up gradation of technology regularly for commercial buildings, high-end housings, malls etc but limited. This needs to be a norm for all the buildings.

Geographical Indictors: Are These Issues or Indicators?

Often the same climatic zones have varied response by the nations and people at large essentially governed by their economies and social setup. For example Asian civilizations is one of the oldest thus their living built environs time tested for use of locally available building materials, indigenous construction technology and typical architectural vocabulary sustainable; an alternative to global construction option. As transportation is rule out in the former one but the only challenge is the scale of development with densities and mega cities one needs to be innovative to continue with the traditional solutions but technology does come in handy. Next for a climatic zone the local population is adapted to it thus their thresholds of thermal comfort also vary. For example use of air-conditioning is the highest consumption in buildings and the global standard of 20 + degrees makes sense for countries of temperate zone but tropical zone population the threshold of 30° when shaded and moderate humidity is comfortable. And as most of the urbanization is to happen in tropical zone and if they decide to go the global way then the energy demands could be catastrophic and jeopardies the sustainability at large. As the UN - SDG vouches health and well being for all, its logical to accept the varying baselines such as that shall be the sustainable approach for future. One may conclude that the energy consumption for the two sets of people shall vary either for heating or cooling, wherein the traditional solutions may help in reducing the energy demands. As a matter of fact there shall be other nations with varying needs for thermal comfort and they too should be dealt such.

Thus key issues may be summarized as follows:

- (1) Climatic zone to be grouped with their historical backdrops that are rich in architecture.
- (2) Thresholds/Baseline for uses of resources – water and energy an offshoot of local DNA.
- (3) For selection of construction to be gauged for its immediate surroundings, urban fabric and regional tissue; as a group of sustainable buildings does not ensure a sustainable tissue.

Socio-Economic Indicators: Are These Issues or Indicators?

The socio-economic context for the nations vary as they all at varying stages of development i.e., for African countries, India and China where pace of urbanization is highest a balance between labour intensive and technology driven execution of buildings etc may be logical; while for the developed nations it may vice versa. Further in the recent past the trend has been developing nations following the 'nature' of development of developed nations and that is alarming; as the solutions adopted by developed nations are in line for their context while duplication in another context shall never be sustainability. When the local economies of

developing nations are growing then the thrust should be contextual – based on circular economy, regenerative economy, and others.

With globalization the economies have diluted the political boundaries and the process is on for social as well. But for the global communities to shape up is a gradual process as it deals with people, their cultures, traditions, their identities and so on. Interestingly the developing nations have young population who are relatively more receptive to changes thus the paradigm shift in some nations faster than the others. Such a volatile situation needs sensitive handling especially from resource consumption point of view.

To sum up the key issue would be:

- (1) Socially acceptable thresholds for resource consumption as they vary from the laid out norms often less than the prescribed ones especially among the developing nations, as they are use to less are more.
- (2) To be aware of their buying capacities and priorities- for example if an air-conditioner is costing more for better rating and technology over a cheaper one with poor rating more often they shall opt for the latter one.
- (3) Lack of awareness and easy access to information too dilutes the intent therefore a standard system recommended with sub sections to address respective issues.

Conclusions and Way Forward

The paper focused on key issues of sustainability indicators of buildings to develop such a framework is an exhaustive exercise and cannot be limited to a paper.

Therefore as a step forward is to on record the key issues which could be carried forward. As UN Sustainable development goals already in place with its fourth revision in place is evolving for efficiency and effectiveness is universally measured. As for the buildings rating systems that essentially focuses on energy issue at large also the output cannot be standardized thus the need to have a universal system that accounts for the three pillars of sustainability. The paper opens up with an overview of the concern with approach to tackle the same by drawing up a matrix of UN SDG and the rating system those have been implemented for maximum buildings. The intention is to be rational in approach so that the evaluation of sustainability indicators to be universal in nature with implementation across the globe.

The way forward shall be to implement the said approach and arrive at a set of sustainability indicators for buildings that can be applied for all type of buildings irrespective of its typology, scale, context and even the climatic zone. The draft cut is in place argued and put out such in the paper but may include the rest of the rating systems as well.

One thing we do know, that we dare not forget, is that better solutions than ours have at times been made by people with much less information than we have.
Wendell Berry

Introduction

Human activities have contributed to global warming and the deterioration of the environment and the planet. These are some of the facts which are being already established by number of studies. It is extremely likely that (95%) human activity is the main cause for global warming since the mid-20th century as stated by intergovernmental panel on Climate Change, IPCC. The three traditional principles like Utility, Beauty and Stability in defining 'Good architecture' are no more enough at the present day context. Architecture has gained a new dimension with an additional term called 'sustainability' as we are entering into a more environmentally-conscious age. Consciousness and appropriate actions are required at each and every stage by all stakeholders involved with the building activities. In India, it is reported that *"India needs to build 31,000 new houses a day over the next 15-years to meet the needs of its rapidly growing and urbanising population"*. One can assess the preparedness regarding management, stock of building materials, availability of proper technology and manpower required in order to attain the target. On the other hand, most of Affordable Housing schemes in majority states are coming up in peri-urban areas or in rural areas in absence of ready, cheap, bulk land in urban areas. The involvement of time, energy and cost in the transportation of so-called conventional building materials like brick, cement, steel, glass, etc., is an issue for these low-budget projects. Moreover, all these materials are either energy intensive and major Embodied energy (EE) contributor. EE is the sum of all energy used in the construction process – right from extraction of raw materials, manufacture of products to their transportation and incorporation into buildings. About 25% of the India's total primary energy demand is because of manufacturing building materials. Government bans on mining of stone, sand and earth, among others will further enhance a major crisis in near future. There is an urgent need to think in a different way by all the stakeholders involved in the building sector in India (Figs. 1 and 2).

On the other hand, India, the largest rice growing country produces around 125 million tonnes of rice with a comparatively low yield level at around 2.85 t/ha. India accounts for almost 20% of all world rice production. This huge production of paddy leaves a substantial quantity of straw on the field at the end of the yield. The farmers burn their field stubble because they do not have the ready options to dispose the straw residuals. The simplest way they find is to burn it locally. The problem of pollution caused by burning of straws in the agricultural states of India is so severe that the US National Aeronautics and Space Administration released a satellite image showing fires across millions of hectares of agricultural fields in the region. The smog and haze it causes even affects the nearby cities. Straw burning not only affects the immediate environment also by generating tremendous amount of heat and by killing the soil microorganisms affecting the soil productivity level but also causes pollution to the overall environment grossly.

Straw is a sustainable construction material that is not extracted from the ground like other materials and does not produce any toxins or pollutions during its production. India being one of the largest rice growing country accounts for almost 20% of all world rice production. Thus the quantum of production of straw is understandable especially in the rural belt where availability of conventional building material is an issue. Generally, in absence of any quick and cheaper option, farmers prefer to burn these straws in order to prepare the ground for the next crop very quickly. The most important benefits of straw bales are environment friendly and low cost due to the availability in abundance as agricultural residues and its reuse as building material.

About Straw Bale

Aiming a more holistic approach towards using sustainable materials in construction, this study examines the viability of straw bale as building material to satisfy our future construction needs in Indian context. As architects, our decision regarding selection of appropriate materials can bring a substantial impact on the environment. Straw bale as a material in construction is the most appropriate answer in handling all issues. Straw is nontoxic, low-cost and carbon-sequestering in nature.

Straw

Straw refers to agricultural byproduct consisting of the yellow dry, dead stems of cereal plants after the grain and chaff have been removed. The cereal grains include wheat, rice, barley, etc. It is different from hay. Straw is the woody hollow stalk of the plant

Fig. 1 Straw bale house at University of Bath, UK Campus. Source: Available at: www.bath.ac.uk/.

Fig. 2 Straw bale Home in Missouri. Source: Available at: <https://blog.shelterpub.com>.

whereas hay is the upper part of it where the grain is located. Straw is rarely used in feeding livestock because of its low nutritional value. Straw is generally used as a waste by-product. It is readily available after every harvesting season and 're-generative' in nature. These straws are very common to soft woods and very similar in chemical composition. It consists of cellulose, hemi-cellulose and lignin. It is estimated that 97.19 MT rice straw is produced in India per annum of which 23% is surplus and left as uncollected.

Straw is a versatile material, has good thermal properties, biodegradable, it is a by-product from agricultural practices with low embodied energy compared to other building materials. Straw can be used as building material in the field where it grows (**Fig. 3**), which is unique for any building material and does not emit poisonous fumes in case of fire. Forever rising inflated housing needs this agro-waste material in the current shortage of wood is a good alternative building material.

Straw Bale

Straw bale usually means a variously-sized, rectangular bundle of plant stems, held together by two or three ties of wire or baling twine and weighing from about 16–43 kg. Bales are rectangular compressed block of straws tied by wire, polypropylene twine or natural fiber twine mostly using mechanical baling equipment preferably at moisture content less than 20%. According to [Myhrman and MacDonald \(2012\)](#), bales are available in two different sizes based on dimensions and number of ties in **Table 1**. The 3-ties bales are more compact denser than 2-ties bales.

Straw bales are available in various other sizes, shapes and weights also meant for various other purposes. These bales can be used laid both 'flat' and 'on edge'. For using straw bales for construction purpose, it is necessary to determine the 'calculated density' (CD) of the bale if it exceeds the minimum standard value. Moisture content is normally expressed as a percentage of the total weight of the "damp" bale, and is calculated by dividing the weight of free water in a bale by the total weight of the bale including water, then multiplying that by 100. The dry weight is used as CD. The densities can vary according to the type of grains, moisture content and the compaction provided by the baler. Most of the US codes specify that a minimum density of 100 kg/m³ is desirable for the purpose of building construction. Bales are usually produced during a short period and it makes sense to buy and

build soon after the new batch becomes available. The bales are not homogenous in nature. **Table 2** shows the harvesting season of different varieties of paddy can give an idea of the possible construction period using straw bales in different locations in India.

Embodied Energy of Straw Bale

Straw has very low embodied energy as compared to most of the conventional building materials (**Fig. 4**) that have high embodied energy, which is the total energy required for producing it; for extracting, processing, transporting etc. This construction method has minimal impact on the environment as the production and transport to the building site of straw bales consumes very little

Fig. 4 Embodied energy in building materials. *Source:* SERT-Sustainable Energy Research Team.

energy. The embodied energy of straw bale is six times lesser than that of the most common material used in conventional construction. Moreover, in a study it is found that by adopting local materials like straw bale the amount of energy used in building decreased upto 215% and the impact of transportation by 453% compared to a concrete building.

The findings can be utilized both in conventional construction industry as a guide in making environmentally mindful decisions, as well as for natural building construction in order to further improve the performance of straw bale structures.

Embodied energy assessment can be done in two stages:

- (1) Measure all the energy requirements and outputs of the process. At this stage sufficient information can be obtained from the technical specifications of a mechanical baler. The efficiency of the baler (meaning how many bales are produced per fuel unit) can be obtained from the manufacturer. Fuel used by the baler is the direct energy requirement of the process.
- (2) Indirect input into the value of embodied energy of straw bales can be identified as energy required for manufacturing of the mechanical equipment- the baler. The composition of the baler has to be established. The second indirect energy input is associated with the construction of shelter needed to keep the bales dry. The energy inputs into the construction of the storage facility must be added.

Thermal Capability

The thermal properties of straw bales depend upon the density of the bales. Load-bearing straw bale walls will require the bales to have a higher density, typically more than 110 kg/m^3 . Non-load-bearing straw bales used for infill can tolerate lower densities, often in the range $80\text{--}100 \text{ kg/m}^3$. Straw bale can have a wide range of densities. Most straw bale codes in the US have chosen to use a minimum density of 7 pounds per cubic foot, (110 kg/m^3) since it is generally agreed that higher density bales are superior (e.g., bales up to 12 pcf are available). Various researches has proved that straw bale has excellent insulation properties. From another study done by the students of Worcester Polytechnic Institute, it is stated that the earthen-based plasters are more thermally resistant than lime-and-cement plasters when applied onto bales. The R-Value of the earthen-plastered bale was calculated to be 10.97 per inch whereas the lime-and-cement-plastered bale was calculated to have an R-value of 7.39 per inch. R-value is the measure of resistance to heat flow through a given thickness of material which actually determine the effectiveness of an insulation material.

Moisture Performance

Despite all its advantages the biggest obstacle to widespread acceptance is the moisture behavior within the straw bale construction, especially as it concerns mold growth. Moisture transfer may cause primarily because of the following reasons:

- Direct wetting from precipitation;
- Water vapour diffusion due to differential pressure across the wall;

- Absorption of rising moisture from the ground;
- Accidental exposure.

Precipitation in the form of rain and snow can be a major cause of concern to straw bale construction if not properly addressed from the very beginning. This will lead to poor durability. Poor durability may again create safety concerns for the occupants and will increase the lifecycle costs of the building. Thermal and moisture performance of straw bale wall systems are intimately related. Moisture performance requires knowledge of heat transfer as some moisture parameters depend upon temperature. Rice is mainly grown in rain fed areas that receive heavy annual rainfall, the reason for which availability of straw will be easy. Thus, adequate attention and precautions need to be taken in the preparation of the straw bales ready for construction and also both in the design and method of construction. As stated by Thomson and Walker (2013), there are several ways to monitor the moisture content of straw bales used in buildings:

- Electrical resistance measurements of timber blocks buried within the wall;
- Indirectly using measured %RH and temperature and determining equivalent straw
- moisture content;
- Direct measurement of the straw electrical resistance with a purpose built probe;
- Gravimetric determination of moisture content through removal and oven drying.

Fire Resistance

The potential for fire lies in the loose straw but not in the straw bales prepared for construction purpose. A compact bale surface normally does not support combustion once the 'fuzz' has burned off. With plaster on both sides, the risk of fire for straw bales reduces significantly. Fire retardant solutions may be applied to straw bale walls with the help of spraying equipment. A study conducted by the students of University of Berkeley shows that the straw bale reflects good fire resistance performance reaches to 30 min fire resistance for non-plastered straw bale and to 2 h fire resistance for plastered straw bale.

Mice and Other Pest Problems

Unlike hays, straws do not have any food content and hence are not an attractive resource for vermin. If plastered properly, the chances of the entry of any kind of vermin is completely eliminated. Since there are voids and gaps in between straws in the bales, there are chances of penetration of mice and other insects. Attention should be there to seal the surface properly.

Structural Stability

The structural components of a building are the foundation, frames, walls and roof. A straw bale building can be constructed in three ways, (1) Load bearing (2) Non load bearing and (3) Hybrid structure. Most of the examples which are available world wide in straw bale construction are low rise buildings with a maximum of two floors. In Indian context, the buildings in rural areas like community buildings, houses, school buildings, health shelters can be designed using straw bale techniques. In peri-urban areas, straw bale walls can be used in frame structures in mass housing schemes. A study says that it takes about 260 three-tie bales to build the six-course high walls (about 8 ft, or 2.44 m) of a modestly rectangular house having an interior square footage of 1500 sq. ft (about 139 sq. m).

Structural load bearing straw bale walls can withstand loads of more than 48,826 kg/m². A wall of "conventional field bales" is able to support a roof load of 600 pounds per foot (900 kg/m), the high-density bales can support up to 3000–4500 pounds per foot (4500–7000 kg/m). The stiffness (E-modulus) of found to be between 0.1 and 0.2 MPa (15–30 psi), depending on density. The bales did not fail or crush in tests which subjected them to over 25% compression, but the useful level of stress was approximately 0.01–0.02 MPa (1.5–3 psi). These values are based on tests conducted by TUNS on oat, barley, and wheat bales from various suppliers, with a density of 55 kg/m³ (3.4 pcf) to 115 kg/m³ (7 pcf). Higher density bales are stiffer.

Acoustic Performance

Straw bale walls are super insulative acoustically. For example, even recording studios in the USA and elsewhere were built of straw bales for their soundproofing quality and insulation. Straw bale wall systems have also been used near airport runways and motorways in US and Europe as sound barriers.

Weather-Resistance

If a straw bale is left out in the field during rain it will become very heavy that can't be lifted due to its weight and will be of no use then. Bales must be stacked off the ground by raising them and covering with a roof they will withstand the weather and the outside edges simply get wet and dry out. Straw does not suck water into itself as concrete does. It simply gets wet as far as the force of the wind can drive the rain into it. When the rain stops, the natural movement of air or wind around the bales dries them out. This cycle of wetting and drying does not damage the bale.

Service Life and Durability

The time period is not certain but it can surely last for at least a century, as there are some straw houses that were built more than one hundred years ago and are still in perfect health. A pre-compressed bale assumes the same characteristics of wood and it can look like a normal brick house.

Design and Construction of Buildings Using Straw Bale

It will be pertinent to discuss few elements related to design and construction in the context of prefabricated construction the design and construction is best suitable in a modular pattern using straw bale. Therefore the scope of modularity and commensurate construction is required. It needs flexibility, user-friendliness and efficiency of space, cost and time to be effective. A general note is given below:

Flexibility

Straw is a flexible material and requires to be work with it somewhat differently than if it was rigid. It is very self-supporting, can resist tipping keep out the wind, inhibiting air or moisture infiltration, resist heat transfer (insulation), reduce water intrusion and migration by storing moisture within the wall, keep the assembly from buckling, under a compressive load and from deflecting in a strong wind, keep the plaster from cracking after it is cured of shrinkage and support the plaster skins from buckling, reduce damage or failure from high winds and earthquakes and stops bullets. In the load-bearing straw bale method, walls of up to 3 stories have been constructed, with infill walls, in post and beam type structures; the straw does not take weight anyway.

End-User-Friendliness

Organic straw is a healthy alternative to modern materials natural and harmless. Living within straw walls can enhance the quality of the air we breathe because it is a breathable material and does not give off harmful fumes such as formaldehyde, as many modern materials do so it helps to keep the inside air fresh. Another health benefit is that when it is coupled with the use of non-toxic organic finishes such as clay, natural pigments, paints, and with opening windows, it can provide one of the safest and most comfortable atmospheres to live and also the ambiance inside a straw bale house is calm, cozy and peaceful. A beautiful, nurturing and safe environment to inhabit needs a high level of sound insulation, air quality and the organic feel to the house. Bales are a healthy choice.

Efficiency

A saving of approximately 10% in the direct cost of the walls is achieved when building with straw bales due to the elimination of formwork the quantity of materials needed is reduced. Due to precast construction lesser waste is generated because of utilization of cheap sources far from the construction site and the shuttering is eliminated with a saving. Similar components when produced repetitively results in faster execution, plenty of productivity and economy. This direct saving in prices is else to the environmental profit of reducing the energy consumption as compared to cement and reinforcing production.

Construction

The construction time for straw bale based buildings is less due to the construction of the prefabricated parts since structural work is confined to constructing the foundations. The building dries out quicker than a building of conventional construction due to low wetness content in the precast modules and is sooner prepared for service. In ready-made housing system, time is saved by the employment of precast elements that are casted off-site as the finishes and services could also be done below the block directly tends to save of money. The construction with prefabricated components takes less time resulting in less expenditure on labor. Up to one-third cost can be saved as compared to a conventionally built home of the same size through prefabrication.

For construction, labor needed to be trained to work on straw bale as the process is different from the conventional process. The baling machine is the most important and foremost equipment that is required before starting the construction. The degree of risk is less than the conventional method as it is not a high rise construction and straw bale can be handled easily. Electric supply is required initially for running baling machine. Water will only be required at the time of foundation casting. Curved walls can be easily made using straw bale blocks but arches and domes are not possible. The mechanical, electrical and plumbing services can be easily installed. Big overhangs are needed to be provided for preventing them from the rain.

A Comparative Statement

Building Materials and Technology Promotion Council (BMTPC) has been identifying and evaluating new materials and construction technologies. These mandatory and desirable criteria should be studied and adapted by implementing agencies to suit their needs.

A number of rapid construction techniques developed both within the country and abroad have been found to be suitable for mass housing projects in the country. Some states have taken initiative to introduce technologies in their projects. BMTPC has also identified, evaluated and recommended technologies: (1) Monolithic Concrete Construction System Using Plastic-Aluminium Formwork, (2) Expanded Polystyrene Core Panel System, (3) Glass Fiber Reinforced Gypsum (GFRG) Panel Building System, (4) Factory Made Fast Track Modular Building System. The reason behind selecting these four prefabrication technologies is that these are technologies which are mostly implemented in housing projects in the India. They are the technologies that are implemented for constructing prefabricated walls and Straw bale construction is also implemented in constructing walls. Above all the parameters like Time Efficiency, Cost Efficiency, Versatility, Structure Behavior and Thermal Behavior on bases of straw bale construction can be analyzed are common in these materials also (Table 3). After comparing straw bale prefabrication housing from other prefabrication techniques the benefits are clear. If the growth of straw bale construction continues, the amount of money and energy that can be saved could reach millions, even billions. If cities began using straw bale as affordable housing, their energy consumption could be reduced by 60%–70%. Moreover, if straw bale construction is used, costs of the building could be greatly reduced. Money saved by using straw bale construction could be applied towards other initiatives in cities. We could easily implement straw bale prefabricated housing for low-income housing. Beyond monetary benefits, its time efficiency, its Versatility the environmental advantages are evident. The use of straw bale rids an agricultural waste that ultimately results in major pollutants. The possibilities of straw bale construction are endless.

Table 3 Comparison of Straw bale with selected prefab materials

1	<i>Straw bale construction</i>	<i>Monolithic concrete construction system using plastic – aluminium formwork</i>	<i>Expanded polystyrene core panel system</i>	<i>Glass fiber reinforced gypsum (gfrg) panel building system</i>	<i>Factory made fast track modular building system</i>
Time efficiency	1/3rd time of conventional construction	1/6th of the X time	One building of two storied (total 1981 sq. ft) was constructed in IIT Madras in one month. <i>Source: www.bmtpc.org</i>	40%	15%–20%
Cost efficiency	10% direct cost saving in walls	15% Cost saving	40% Cost saving	20%–30%	30% cost saving
Versatility	By-product from agricultural practices, bio-degradable, good thermal properties and low embodied energy	Designed for any condition/ component of building such as bay windows, stairs, balconies, and special architectural features. <i>Source: aluminiumformwoktechnology.blogspot.in</i>	Panels can be easily anchored to other construction elements, such as steel, wood, and pre-stressed concrete. <i>Source: naredco.in</i>	Panels can be used not only as walls but also as floors, roofs and staircase. <i>Source: naredco.in</i>	Structure can be transported and erected fast due to its lightweight.
Structure behavior	Straw bale walls can withstand loads of more than 48,826 kg/m ²	Resistant to earthquakes than the traditional RCC column and beam designs. <i>Source: aluminiumformwoktechnology.blogspot.in</i>	Withstand a maximum load of up to 1530 KN/m $\approx$ 153 ton/m, have a low seismic mass. <i>Source: naredco.in</i>	Filled with reinforced concrete, possess the substantial strength to act not only as load-bearing elements, but also as the shear wall. <i>Source: www.bmtpc.org</i>	Less earthquake force generation is due to light weight. Highly ductile and load carrying nature of closely spaced studs/joists. Very light structure does not require the heavy foundation.
Thermal behavior	R-value between 40 and 60. A good thermal performance than the other walling materials	100 mm RCC Walls and Roof has thermal transmittance value as 3.59 W/m ² K (as per IS 3792:1978)	80 mm core and finished thickness of about 15 cm provides the same thermal insulation as an insulated solid masonry wall of about 40 cm. <i>Source: www.bmtpc.org</i>	Compared the traditional system with GFRG system, the thermal comfort performance was almost the same

Production of Straw Bale Prefab Components

Using any material as prefab material is different than the conventional construction. It needs systematic planning of the prefabrication process. General process of prefabrication is given as, design (modular coordination), production, supply, assembly and quality controls. However, for doing this, there are many offsite and onsite conditions. The materials suitability for modular construction in the given geo-climatic region could be the onsite construction related elements taken care prior to production of components. Following that it needs land, investment, offsite infrastructure, skill development and quality control for a successful prefabrication process of building components. Few of those concerns for prefabrication is discussed below:

Land for Setting up Prefab Plant

Apart from the comparative advantage on structural behavior, thermal behavior, versatility and efficiency as shown in the table on the preceding page it is also to be mentioned that straw bale will be more affective in rural areas when considered off site considerations of prefab productions. Firstly, the supply of land for setting up of manufacturing plant will be cheaper in rural areas than urban areas. The quantum of land required for agro based factories for straw bale will be small mid-sized and not some large industries. This makes it more feasible options. It is highly possible that the straw growers make cooperatives as in the other agricultural cooperatives and makes smaller plants. This in fact could be more viable options if right kind of government facilitation is provided. The existing land acquisition act (RIFCTLARR Act 2013) provides much ease of any such land related investment when land owners offer mutual consent. Nevertheless, we find a win-win possibility of such prefab plant since the whole life cycle of the materials is rural and agro based. In return the adjoining areas and villages will be benefitted with more employment and jobs. This should motivate the policy and decision makers.

Investment for Prefabrication

The land requirement is directly related to the capital investment for the setting up of plant. The initial investment thus will be much lesser than any prefab plant in the cities and peri-urban areas. The cost of raw material is almost negligible since straw bale is essential byproduct of agriculture. As mentioned earlier, it will maintain the sustainability of use and reuse of straw bale. A very important evidence of this sustainability of this material could be taken from large tract of Himalayan belt in India where straw mixed clay is used as filler materials in the framed construction. the easy availability of straw and its sustainable supply due to food production is the unique reason for its popularity in rural areas of India and elsewhere. Thus the advantage can be taken for the prefab panel productions. The initiatives by farmer's cooperatives and other community based organization can also explore such opportunity. The industrialization of building components thus, could be much different in rural India than the urban counterpart in the country and other industrialised countries where mainly it came through the private investment.

Training and Skill Development

We find a gradual depletion of the sustainable construction practices in rural areas and hilly areas in India in spite of such abundant supply of agri-based raw materials. One of the reason for this is the changing economic dimensions in the country. The cases of migration from rural to urban and cities to large cities are common. The tradition practices of construction are forgotten. Traditional and indigenous practices of sustainability are on the back seat. The concrete and steel has taken over the vernacular practices in most of the indigenously rich regions of India. One of the silent reason for this is the absence of organized practice of the traditional construction systems and continuity in training and academics. The straw bale as prefab materials will be successful if it is connected to a suitable training mechanism along with the investment and manufacturing. There is a great concerns of prefabrication worldwide are the acceptance of the product. In this case if the people are involved in the whole life cycle of the materials and building construction there is a high possibility of successful prefabrication. The training and ICT ecosystems at the village panchayat level in the country could be linked with such training. It is to be noted that the training has to be linked with the practice. In 70s the setting up of building centers in the country by HUDCO failed to the missing link between the training and practice. That lesson must be considered. Inclusion of straw-bale as prefab construction in the academic courses of architecture and civil engineering will also be needed.

Quality Control

Quality control in prefab construction is great concern. In a closed system the whole quality control is maintained by a single manufacturer. The city authority and quality control authority as the case may be provided technical norms and guidelines. In India, the required step could be the formulation to relevant building codes for straw bale construction. It is highly recommended to have a semi-prefabrication in the case of straw-bale construction. The quality control has to be linked with the training, institutional mechanism and involvement of local governance set up to get the maximum benefit.

Fig. 5 A straw bale house construction with pre fab construction. *Source:* Available at: <https://in.pinterest.com>.

Offsite Infrastructure

In the prefabricated building component supply chain the offsite infrastructure takes a major role. The transportation of raw material and supply of finished materials need finished road to withstand the load of prefabricated transporters. In this case the need for offsite road infrastructure will be minimal. The catchment of raw materials seems not more than 5–10 km which can be transported with metalled rural roads in India as built during PMGSY and with the basic vehicles including animal driven carts. For the supply of finished product, the same network can be used through the use of animal driven cart and small vehicle. This definitely makes straw bale as unique than the other prefabricated materials. The onsite and near site movement can be even manual since the weight of components are not heavy (see earlier sections).

Straw bale prefabricated modules are needed to be carefully designed so that they will be accepted as any other conventional alternatives that exist on the construction market today before introducing them to the construction market emphasizing on that they will perform as they are supposed to. The new material must be easier to manufacture, transport and assemble as existing systems and methods and also needs to be economical as compared to the existing materials (Fig. 5).

Keeping in view the present Indian context regarding the other prefabricated materials discussed above it is proposed to have straw bale construction housing consisting framed structures and made of prefabricated components to achieve a cost-effective and socially acceptable housing supply for Economically Weaker Sections and Lower Income Group who mainly forms slums or unauthorized construction in urban areas. Straw is an answer to solve the housing demand for the growing population in India. Enough to build millions of homes as it is available abundantly due to its production every year with the production of cereals all over the country so incorporating straw in home construction. The straw bale can accommodate the future need of construction if it will enter the industrial construction market and it is capable of reducing emissions, storing carbon, reducing waste and saving both energy and non-renewable resources.

Straw bale construction is capable of ticking all of those boxes if approached properly. Straw edges from intrinsic 'green' values, inaccessibility while not the requirement for specialist skills and a robust support network. It is proved that straw bale building has a good thermal performance than the other walling materials in tropical climatic conditions. It was found that the straw bale construction is a good alternative for common walling materials and also this will be a cost-effective construction method.

Conclusion

Strawbale is ideally suited to dry hot climates, cold climates and temperate climates with hot/cold seasonal swings. Wide wrap-around porches, trees for shade, capturing breezes, natural ventilation, good design to guard against roof leaks, and other factors are important considerations to be kept in mind while designing the site plan with straw bale construction. Straw-bale construction is an excellent choice for cold climates. Its ability to provide affordable super insulation is unsurpassed. Building of Straw bale houses are possible in rainy climates also, and if properly detailed, will last for many years without moisture problems. In India, some of the states are 3-crop regions where bulk straw is produced as a waste-by product. There is a promising possibility of using this stock as a pre fab material in the construction in meeting the huge demand of built up area for different purposes in the country.

Improving Building Technologies With a Sustainable Strategy

Jayashree Deshpande, COA Training and Research Centre, Pune, India and Academic Wing of Council of Architecture, New Delhi, India

© 2020 Elsevier Inc. All rights reserved.

The daily headlines scream of the looming energy and water crisis. Accelerated urbanization, supplementary spending power and a desire for an improved life style demand buildings, which are increasingly complex and insensitive to the context of contemporary environmental concerns. The lifestyle, attitude and demands of the urban populations all over the world, display a voracious appetite for material affluence which is directly proportional to dependency on existing energy resources.

Traditional architecture has been constantly innovative, so that structures have presented a series of logical solutions to the problems of the climatic conditions, while attempting to enhance human comfort and productivity. On the other hand the practice of design, construction, operation and maintenance of buildings in present times, utilizes colossal amounts of energy, water and raw materials, and at the same time generates large quantities of waste, causing severe environmental pollution. Designers, in an effort to meet the growing demands of lighting, ventilating, cooling and heating are regularly providing solutions which are energy intensive and inflict tremendous pressure on the rapidly diminishing energy resources. Excessive consumption of land, water and energy resources during the construction of buildings and their life span is having a negative impact on the fragile ecosystems leading to environmental degradation.

At this stage it may be appropriate to examine the meaning of the term 'sustainable development'. There are various definitions in use but it is difficult to put a precise meaning to the term. Development is about improving the well-being of people, raising living standards and increasing facilities whereas the closest explanation of the term sustainable would probably be 'long lasting'. Today, it appears that development is proving detrimental to sustainability. Spiraling energy prices too accentuate the significance of material and resource conservation. There is, therefore, an urgent need to foster thinking which redefines a cordial relationship between the building and the environment such that practical solutions given against traditional patterns of social and economic development circumvent set parameters to improve the quality of the surroundings, produce surplus power and food, and convert waste into nutrients and useful products.

Buildings are integrated systems that continuously interact with their surroundings. The process of architectural design is complex and involves interaction amongst parameters of diverse nature and varying magnitude. It is therefore mandatory to develop and define a process of architectural design that is scientific and leads to sustainability. In the present scenario, the energy and water crises would continue to worsen, and so will the associated negative impacts of pollution and environmental degradation, unless urgent steps are taken to control unsustainable design practices.

Sustainable building practices and technologies seek to reduce and decelerate the depletion of natural resources of energy, water and ground cover and promote the process of eco-friendly habitat. Intelligent architectural design strategies can enhance building performance. It is very important, therefore, to develop and implement specific design strategies and construction techniques in order to decrease energy consumption and move towards sustainability. It is equally important to consider the mode of designing buildings with an integrated approach which simultaneously incorporates climate responsive design strategies using eco-friendly materials to create 'Sustainable' buildings that enhance users' comfort. Further, varied materials and methods of construction can be used to establish a harmonious co-relation between sustainability, affordability and the contemporary built environment.

An integrated approach to design, incorporating bio-climatic architectural design principles, responsive to the climate of that region goes a long way towards minimizing the load on conventional heating, cooling, ventilating and lighting systems. 'Sustainable' buildings so designed, minimize the negative impacts on our fragile environment while enhancing users' comfort and productivity. The overall energy performance of buildings can be substantially enhanced by adopting sustainable principles promoting the use of efficient design strategies, renewable energy systems, and environmentally friendly materials and technologies. This results in a substantially reduced ecological footprint (Fig. 1).

The process of sustainable building design needs to be addressed right from the schematic design stage using scientific methods of:

Analysis	Understanding the problem and its context.
	Characterizing important requirements.
	Establishing relative priorities.
	Determining desired objectives.
Application	Formulating climate responsive, sustainable design strategies.
	Applying strategies which simultaneously establish relationships between architectural form, space and energy consumption.
Evaluation	Monitoring the performance of the building.
	Evaluating the performance against established priorities and objectives.

Fig. 1 The ecological footprint.

Concerns for the Designer

One of the most challenging problems associated with design and construction of a sustainable built environment is the optimal energy management with respect to manifold and often contradictory objectives. In order to establish a meaningful balance between energy saving and a comfortable lifestyle, designers are continuously innovating to develop techniques capable of providing a high level of comfort for users, together with a lower energy consumption needed to meet environmental regulations and minimize electricity bills. To minimize power consumption, the energy used by the building has to be optimized and effectively managed right from the stages of the initial design, period of construction and throughout its entire life cycle. Techniques for reducing consumption in high-use buildings and upgrading the comfort levels of users with optimum consumption of energy need to be consciously implemented. Integrating devices and components in the architectural fabric, providing optimum light and ventilation using centralized/active or decentralized/passive renewable technologies, reducing the water and energy embodied in materials and construction, and reducing waste and reusing or recycling building materials are some of the important concerns for designers.

Efficient Design Strategies

To increase the sustainability quotient of a building, a variety of active and passive design strategies can be incorporated. Active strategies involve the direct use of heating and cooling systems, while passive design measures include working on building orientation, air sealing, continuous insulation, openings and daylighting calculations at the initial design stage of a building to take advantage of natural lighting and ventilation opportunities during the useful life of the building. Some of such measures could be:

- Astute application of design principles for orientation, building envelope, design of fenestration and shading devices, building form and shape, surface-volume ratio, passive solar design, conducive to the availability of natural lighting and ventilation to help in minimizing energy loads.
- Use of advanced concepts of passive heating like use of direct or indirect gain systems, sunspaces or passive cooling concepts like evaporative cooling, wind tower, earth air tunnel etc. may be considered in lower operating costs.
- The landscaping character can greatly alter the microclimate of the place and serve to reduce direct sun striking and subsequent heat build-up. Appropriate treatment of landscaping elements, vegetation and water bodies can decrease temperatures by evaporative cooling and create advantageous air-flow patterns resulting in desirable ventilation.
- Use of solar energy for water heating, wind energy for electricity, water conservation, rain water harvesting for ground water recharge, solid waste management can further contribute to the aim of reducing the strain on conventional energy sources.

Such design strategies, if adopted judiciously can go a long way in the creation of affordable, sustainable habitat.

Fig. 2 Properties of environment friendly building materials.

Environment Friendly Building Materials

Traditionally man has depended heavily on nature to provide the basic materials for the construction of his dwellings. The cost of conventional building materials like burnt bricks, steel and cement is high and they utilize large amounts of non-renewable natural resources like minerals, top-soil, forest cover etc. They increase the dependence on external materials and manpower, harm the local ecology and are generally polluting in nature (Fig. 2).

The materials and technologies chosen for construction, should, in addition to functional efficiency, fulfill some or more of the following criteria, for the cause of sustainability and a better quality environment. These technologies should:

- not endanger bio-reserves
- be non-polluting
- recycle polluting waste into usable materials
- utilize locally available materials
- utilize renewable energy sources
- be accessible to the people
- utilize local skills, manpower and management systems
- be self-sustaining and promote self-reliance
- benefit local economy by being income generating
- be low in monetary cost

Embodied energy consumption in building construction is optimized by the use of locally available or recycled materials and new materials with desired properties. Environment friendly materials demonstrate one or more of the characteristics like renewable source, high reused or recycled content, low level of emissions, smaller toxicity content, durability, longevity and local production. Judicious choice of building materials can be made by evaluating several characteristics on a comparative scale. An understanding of the lifespan of a material, the energy input and waste output at each stage can form the base analysis in the selection process. Use of low-energy materials contributes significantly to materials efficiency. Ferro-crete, substituting steel with wire mesh and eliminating aggregates, bamboo reinforced concrete components, terrazzo flooring tiles using waste chips of broken tiles, stones and ceramic articles, interlocking porous concrete paving blocks, bricks and building blocks manufactured using industrial waste, mine wastes and rejects, fly ash in combination with burnt clay, cellular concrete, pulverized debris are few of the available eco friendly materials.

Appropriate Building Technology

Although a range of environment friendly materials is now available in the market, there is a need today, for developing cost-effective, sustainable, building techniques using locally available materials which are strong and durable yet esthetically pleasant. Over the years, innovations and developments in construction technology have provided the impetus to create relevant tools and techniques of construction such as the inverted saucer foundation, universal building blocks for internal and external walls and filler slabs. Moreover, the use of solar energy for electricity, bio gas for cooking and hot water, rain water harvesting for ground water recharge, water conservation methods and solid waste management play a significant role in reducing the strain on conventional energy sources.

Fig. 3 (a, b) Filler slab using overburnt bricks.

Indigenously Developed Brick Bonds

Substantial reduction in unnecessary use of excess building material in the construction of brickwork, while maintaining required strength, can be achieved by the use of indigenously developed brick bonds. Variations of the traditionally used brick bonds have been developed and used in various parts of Maharashtra, India. The indigenously developed 'Joshi bond', for one brick thick walls, can save up to 20% by the use of bricks laid on bed. The Joshi cavity bond, (modified rat trap bond), for one and half brick thick walls can effect a saving of up to 35.7% for bricks laid on edge, while the Joshi cavity bond, for one brick thick walls, used for internal partition walls can effect a saving of 25% in the quantity of brick used.

Filler Slabs

A unique modification of the filler slab construction technique, replaces the redundant concrete in the slab with light weight, damaged and therefore discarded or reused, clay tiles (Mangalore tiles) and ordinary bricks bats. The use of Mangalore tiles as a filler serves the dual purpose of providing thermal insulation from the heat of sunlight while simultaneously reducing the weight of the slab due to reduced quantity of the concrete. As a result of reduction in the dead weight of the slab, the spacing of the steel can be increased, effecting a reduction in the consumption of steel. Experiments in using filler slab instead of regular slab show an effective saving of 30%–40% on steel & concrete (**Fig. 3**).

Shutter Less and Frameless Windows

Specially designed cement concrete window panels prove to be very economical in terms of cost of material and construction. They can be used to form shutter less, frame less windows without weather shade (Chhajja). The special cement panel pattern is designed and cast locally. The panel is designed to have horizontal strips having a downwards slope on the external face with a provision to fix 6 in. wide glass strips. Rainwater will slide down over the glass and flow away easily without penetrating into the room. The glass strips also allow penetration of light into the room while preventing glare and providing privacy. These window panels when placed on the windward side permit even distribution of air in the interiors. The use of this type of narrow and extra height windows without frame and shutter, eliminating the use of chhajja costs only about 10%–15% of the total cost of a normal window with shutters & chhajja (**Fig. 4**).

Fig. 4 Pre cast cement concrete window panel.

Fig. 5 (a, b, c) The inverted saucer foundation.

Fig. 6 Biogas plant.

Fig. 7 Wall constructed using universal blocks.

Inverted Saucer Foundation

This form of foundation is ideal for black cotton soil. A large proportion of the load of building is spread on the upper surface of the ground and expenditure on piles and deep foundations can be avoided. Additionally, each footing requires only one third the quantity of cement as against the total quantity of cement required for a normal footing. Inverted saucer footings are also resistant to earthquakes as the cavity formed inside the hollow of the footing is filled with loose sand which can absorb seismic movements ([Fig. 5](#)).

Use of Bio Gas

As an alternative to unhygienic soak-pits or septic tanks, toilets can be connected to Cowdung (gobar)gas plants or biogas plants. Depending on quantity of flow, a constant or regulated intermittent flow of gas can be available for purposes of cooking or heating. Additionally good quality organic manure can be generated. The bio gas plants require minimal regular maintenance ([Fig. 6](#)).

Fig. 8 (a, b, c, d) Bamboo as substitute to steel reinforcement in slab, parapet, staircase and piles.

Universal Cement-Aggregate Blocks

Conventionally, bricks used for building construction have three dimensions namely the header, the stretcher and the height. While using in traditionally preferred English or Flemish bonds, variation in dimensions, requires trained and skillful masons, and also considerably reduces the speed of the construction subsequently increasing use of mortar. Universal blocks of size 20 cm × 20 cm × 20 cm cast out of 25% cement mortar and aggregate reduces the quantity of cement used in the construction considerably. The ease of laying the blocks increases the speed of construction. No continuous joints, vertical or horizontal should be allowed throughout the length and height of the wall unit. This block standing on its edge has the maximum load bearing strength and maximum resistance to buckling. It also has a good

lateral stability due to optimal slenderness ratio. The complimentary units derived from the basic block above are $10\text{ cm} \times 20\text{ cm} \times 20\text{ cm}$ and $10\text{ cm} \times 10\text{ cm} \times 20\text{ cm}$. These serve as bats and/or closers. By eliminating the use of some blocks a perforated wall can be designed. These small openings if arranged in sufficient number by precise calculation, can serve as ventilators allowing desirable ventilation and reducing the glare, which is highly preferred in the tropical climates. This construction detail helps to eliminate lintels, chhajjas and grills for windows, thereby effectively reducing the cost. The time of construction is substantially reduced, as time for fixing the windows, casting the lintels etc. is eliminated. The bond using the universal blocks is named as “Universal Bond” and has several documented variations. Almost 216 variations are possible with these three units. In practice it is seen, that if a mason goes wrong, he changes the design but does no harm to the strength of the wall. All the waste material obtained from demolished buildings can be recycled irrespective of type or size and utilized in the universal blocks. About 8%–10% cement by weight is required for each block. They can be cast by hand or with the help of a machine. Intelligent use of a wood piece as a rough ground, while casting the specific blocks to be used on the peripheries of openings, helps to eliminate the need of doorframes. Documented examples have shown that small self supporting walls of approximately 8 feet height and 10 feet length can be erected without any lateral supports, columns etc. using universal blocks (Fig. 7).

Use of Bamboo as a Reinforcement Material in RCC

Bamboo as a natural material is renewable and biodegradable in nature. It is energy efficient on account of its natural origin and environmentally sustainable nature. These properties have encouraged the use of bamboo in the construction field for several years. Bamboo has been used for scaffolding works, formwork supporting stands and in many medium and large building construction projects. Bamboo based products like bamboo based particle boards and ply boards, bamboo matting are considered environmentally friendly and are used regularly in construction. Bamboo has been used mainly as a strength bearing construction material for building shelters for centuries in certain regions. However, its application as reinforcement in concrete is fairly recent. It is observed that bamboo reinforced concrete construction can follow the same design, mix proportions and construction techniques as used for steel reinforced concrete. Only steel reinforcement is replaced with bamboo reinforcement. On account of high demand of steel as a reinforcing material in developing countries, there are situations when the production of steel is inadequate to meet the demand. It is noted that the property of tensile strength which is the main requirement of a reinforcing material is quite appreciable for bamboo as compared to other materials. Fast growing bamboo can be cultivated in abundance and can probably satisfy the demand as a reinforcing material to become an ideal replacement for steel (Fig. 8).

Conclusion

Climate responsive design strategies using eco-friendly materials and technologies can become the means to create ‘Sustainable’ buildings. Although a range of environment friendly materials is available in the market, efforts at innovation, seeking to provide logical solutions to the problems of the climatic conditions, in order to enhance human comfort and productivity should be promoted. Generating an awareness in the masses, documenting and acknowledging efforts of individual practitioners of sustainable techniques, encouragement to industrial units by way of incentives from local bodies, and educating clients and builders in areas of sustainable practices can go a long way to help protect the environment.

"The world we have made as a result of the level of thinking we have done thus far creates problems that we cannot solve at the same level at which we have created them...We shall require a substantially new manner of thinking if humankind is to survive" Albert Einstein

Introduction

"The future is not some place we are going to, but one we are creating. The paths to it are not found, but made; and the activity of making them changes both the maker and the destination" says John Schaar. It is no denying a fact that technological innovations have contributed a lot in the field of Architecture and the benefits are being enjoyed by the people for couple of decades. These emerging technologies not only affect the user behavior but also have an overall impact on society. Collingridge says 'The social consequences of a technology cannot be predicted early in the life of the technology. By the time undesirable consequences are discovered, however, the technology is often so much part of the whole economics and social fabric that its control is extremely difficult'. Today the world can witness the tallest (163 floor storied) structure only because elevators were invented in the year 1853. Researchers from University of Missouri-Columbia have found in a study 'Taking The Elevator Could Be Worse For Your Body' that a reduction in daily physical activity is an actual cause of many of the risk factors for chronic diseases, including diabetes and cardiovascular disease. Because of the availability of the elevators, the concept of 'walk-up' apartment is vanished from the society. Even for a double storied building also, people are preferring to install an elevator at the cost of one's health. The installation of an elevator is not only inviting the health problem of the occupant but also involves huge amount of energy cost. The energy component is quantifiable whereas the impact of other components like health, social, behavioral, etc., is not. Designers need to understand the dynamics between technology and society. A piece of technology attain its meaning and stable function in a society, thereby providing a conceptual foundation for design methodology. At present, there are few rating systems available in most of the countries which have become a framework of reference to assess and measure the sustainability of buildings. But there are no mechanisms available by which the quantification of other factors can be done.

All design projects have certain forces (as mentioned in Fig. 1) which are always pulling them in different directions. Among these forces, some are 'definite' in nature (in purple and brown) and some are 'indefinite' (in black) in nature. For the purpose of this study, we will limit our discussion regarding 'usability' and 'material selection' only.

Universal Values and Design

Architecture is the discipline dealing with design focusing on the creation of physical environments. Designing a built environment is not merely satisfying the functional space requirements of the user. Integration of the individual and social values into the design process has become equally important to meet the sustainability goals. In architecture, a firm relation between values and design is present throughout the history. 'Architecture can communicate memory, but it can also communicate values and a sense of place.....Architecture is an expression of values – the way we build is a reflection of the way we live.' says Norman Foster. Values underline all the acts which we feel we have chosen. The question is 'Can moral values be considered as universal?' A value can be called a universal value if it has the same value or worth for all, or almost all people. At the same time, it is interesting to note that the design values and perception as read by the architecture fraternity often varies from that of the civil society. On the other hand, there are certain universal values which are accepted by all in a similar manner.

Fig. 1 Different forces in Design process.

'Satyam-Shivam-Sundaram' which means Truth-Goodness-Beauty is considered as universal values by everyone since time immemorial. A rose appears to be a beautiful creation in nature is an accepted fact by everyone which can be considered as an universal value.

Values become deeply embedded into the architectural design process. Thus if the universal values are similarly understood or recognized by all, then how the interpretations by the architecture fraternity and the civil society are different? Sharon Knoll says 'The domain of interpretation contains how we label or describe our experience. It includes analysis, evaluation, assessment, "knowledge", opinion, stories, etc. It also contains reflexive responses/reactions, unconsciously inherited perspectives, and the foundation/justification for saying that someone or something is "right" or "wrong".'

The preservation of options for the future can be readily linked to notions of equity if it is agreed that "the future ought not to face, as a result of our actions today, a seriously reduced range of options and choices, as they try to adapt to the environment that they face".

Concept of Responsible Building

What is 'Responsibility'? Sharon Knoll says 'For most of us, responsibility is held as burden, blame or guilt. Responsibility has become something to be avoided.....Responsibility can be embraced as a powerful relationship to circumstances.' In this context, it would be pertinent to mention that till date there is no such proper definition about Responsible Building. On the other hand, lot of definitions of 'Sustainable buildings' are found available over the last few decades. The U.S. Environmental Protection Agency (EPA) stated that sustainable building is the practice of creating structures by using processes that are environmentally responsible, resource efficient and impact minimizing in their life cycle from siting to deconstruction. In absence of any such definition of responsible building, an effort is taken to find out how other disciplines are capturing the concept in today's context. It is found that 'Responsible Innovation' is defined by Jack Stilgoe and co researchers as "taking care of the future through collective stewardship of science and innovation in the present". In a training workshop 'Designing for Socio-Ecological Transformation' organized by ECO-LOGICAL Foundation in collaboration with FES, India the discussions on 'Responsible Building' were held and after several deliberations the concept (Fig. 2) was developed. It is clear that a responsible building needs to be responsible throughout its existence on the mother Earth right from the beginning. Responsibility starts with the design process and gradually

Fig. 2 Responsible Building. Conceptualized and developed by Vinyas based on the dialogue in Kandbari, Himachal Pradesh, 2014.

it increases at each and every stage even after its death also, a building has to be responsible. It means the thought process involved with the building activities has to be responsible.

Value Judgement: Way Towards Responsible Design

When we are discussing about universal values in the context of taking design decisions for achieving energy efficiency in buildings, it is imperative to understand what is 'value judgment' and how it can lead to create responsible design. A value judgment is a judgment of the rightness or wrongness of something, or of the usefulness of something, based on a comparison. Different theories on engineering ethics have defined value as a principle that promotes well-being or prevents harm. Values are the scales we use to weigh our choices for our actions, whether to move towards or away from something. Through value judgment one can be sensitive towards the beliefs, values and identity of society that has usually been acquired through layers of experience and actions, which can enable to take responsible environment responsive design decisions.

While focusing on responsible design, knowledge about social, ethical, environmental, economic values and issues involved in design is required to make informed, considered and sensitive value judgments. Design quality can be evaluated as an overall value judgement of stakeholders involved in the entire process of design, construction and use of the built space, which is based on their respective interaction with different aspects of the built environment. As a result of the interaction between the individual and the product, a value judgement is always accompanied by an emotional response and an assessment about the level of quality or value of a product.

Responsible design focuses on creating functional feedback loops between social and environmental systems, while avoiding superimposition of preconceived stereotype ideas. Before providing the building design for construction, several field studies, stakeholder discussions, assumptions, conceptual plans, design and redesign, and climatic efficiency test by using different computational simulation technique are conducted several times till the design fulfills all functions satisfactorily. Different materials and construction techniques are tried and tested in the design process. Building design should be an iterative process to enable value judgment in creating an environment responsive built space.

Right Environmental Actions: Ethical Approach for Responsible Designing

Ethical theories and principles stresses upon how to live, to respond to issues, through the duties, rights, responsibilities, and obligations. The principles and practices have varied over different geography, climate, period of history and society. But, ethical behavior that focuses on responsible actions is being advocated beyond the limits mentioned above and these principles and practices have universal value and inclusive applications. Two basic questions are in the forefront in the discourse on environmental values (a) What kinds of thing are intrinsically valuable? (b) What makes an action right or wrong for the sustenance of environment.

Environmental ethics often draws conceptual thinking from traditional ethical systems and theories. "Human-environmental interaction in a specific place, including the management of common pool resources, needs to be situated within the historical, ecological and cultural narrative of its human ecology" (Rourke, 2005). Environmental principles acknowledge the moral relationship of human beings towards environment, and also the value of environment and its non-human contents. Pro-Environmental actions include the attempt to apply traditional ethical theories, preservation of biodiversity as an ethical goal, and broader concerns of the built environment along with the politics of poverty; and climate change (Brennan and Yeuk-Sze, 2016).

The consciousness and emergence of activism for right environmental actions brought in the slogan of 'Sustainability' into most of the development agenda. The Brundtland report depicts sustainability as a challenge and opportunity for the world to become more socially, politically and environmentally fair. In pursuit of intergenerational justice, it suggests that there should be new human rights added to the standard list, for example, that "All human beings have the fundamental right to an environment adequate for their health and well being" (WCED, 1987). With depleting natural resource and impending climate change, it is important to examine 'How much is adequate?' and 'What is the optimum level?'. The term 'Utilitarianism' conceptualized in the 19th century by Jeremy Bentham and John Stuart Mill which suggested that the standard of right conduct is maximization of good consequences. But, to find a solution to the above posed questions, the good consequential effects drawn by utilitarian approach are required to be achieved with minimalist ideas and techniques. Herein, the principles of reduce, reuse, recycle, recover and replenish coined by Bwrgkamp *et al.* (2015) for sustainable development and discussed in the Directive [2008/98/EC] of the European Parliament and of the Council on waste have meaning in the context of right environmental action, and which can be the guiding principles for responsible design.

Naagarazan (2006) puts forth the following points while analyzing an issue with an utilitarian approach:

- Various courses of action that are available are to be identified.
- Next it is to be examined who will be affected by each action and what benefits or harms will be derived from each of these actions.
- Then the action that will produce the greatest benefits and the least harm is to be selected. The ethical action is the one that provides the greatest good for the greatest number.

Fig. 3 shows the issues and requisites a professional has to act upon for making environmental sensitive responsible design decisions.

OBJECTIVITY
Cost and benefits of all possible alternative means in objective manner. Skill in comprehending, clarifying, and critical assessment of contested ideas.
BACKGROUND KNOWLEDGE
Understanding of economic and functional viability (effectiveness), environmental and technical achievability (efficiency), operational feasibility (post occupancy) and social acceptability, which include environmental and ethical aspects. Awareness of alternate responses to issues and creative solutions.
VALUE
Qualities, such as <i>competence (skills and expertise), diligence in delivering decisions, loyalty in meeting the interests of users, public trust, and respect for the common good, rather than serving only the interests of the clients or the political interests.</i>
TECHNICAL COMPLEXITY
Unrealistic assumptions and frivolous design decisions goes against environmental ethics, and increase in embodied energy. Energy options, assumptions on population increase, life style, urbanization, availability of local fossil resources, projected costs of generating alternative forms of energy and adoption of alternative construction technology may increase the complexity in judgment on future. Sensitivity to genuine difficulties, including willingness to tolerate uncertainties while making decisions.

Fig. 3 Professional issues and requirement. *Source:* Naagarazan, R.S., 2006. Professional Ethics and Human Values. New Delhi: New Age International Publishers.

Usability in Architecture

In software engineering, usability is the degree to which a software can be used by specified consumers to achieve quantified objectives with effectiveness, efficiency, and satisfaction in a quantified context of use. Usability in Architecture is based on the prevailing norms and standards for each building functional use. The amount of air, daylight and the space per person are also mentioned in the Architectural standards. Standards might change with time and context. An efficient building should be able to adapt to all the upcoming changes which might be required by its users in future. Usability is present in all interactions between user and object. Architects need to think about the solutions which can create an adaptable intervention so that it becomes easy to incorporate future modifications within enclosures. At present, a majority of architectural creations is based on studying human behavior and patterns. Architectural designs are mostly carried out based on past experiences following certain norms and standards. In most cases, the design briefs are generally prepared by the architects in consultation with the client. The outcome often comes as a product where it is found a certain amount spaces are either un-utilized or under-utilized. A space when remains un-utilized or under-utilized in turn is a wastage of energy and resources. Thus thinking of optimizing space requirements in design will also help in reducing the carbon footprint on the globe and a responsible way to look at it.

Integrated Holistic Process: Enabling Sustainable Design

Meeting the ever expanding human needs in the face of declining resources and changing climate is a challenge posed to all the stakeholders involved in taking decisions regarding building design and construction. As more issues, perspectives, models, codes and metrics are incorporated into the planning and building process, the roles of engineers and designers are increasingly being fused (Sarté, 2010). Designers are to be equipped with expertise to incorporate systems thinking, take account of material flows, and infuse environmental performance concepts into their work. Engineers are to be more involved from the initial stage by applying their technical and infrastructure related expertise earlier and more comprehensively as an integral part of a holistic design process. There is a need to address critical questions regarding planning, designing, and building healthy, cities, homes and communities for a growing and demanding population, along with the provision of efficient utilities and infrastructure in ecologically sustainable manner.

There is a need of integrated creative technological approaches for designing, redesigning and retrofitting the built environment, where the role of architects, engineers, building science experts, ecologists, landscape architect are elucidated at different stages in the collaborative design process necessary for developing effective integrated solutions. Recently these types of integrated design team are working together around the world by incorporating ecological infrastructure into buildings by using different environmental approaches and techniques; eg. reuse of storm-water, recycle of grey water, solid waste, application of alternative building construction techniques in an aesthetically environmental friendly way, incorporating creative solar passive design ideas to build more beautiful communities and by designing urban environments that respect and engage natural systems. (Table 1) The infrastructure solutions can emerge from a process of on- and off-site collaborative thinking involving a wide array of stakeholders.

Table 1 Framework for five pillars of sustainability for optimizing system synergies and advancing towards regenerative designs

	<i>Level one: Reduce Harm</i>	<i>Level Two: Sustainability sourcing</i>	<i>Level Three: Systems Integration</i>	<i>Level Four: Regenerative Design</i>
Community	(1) Integrate project into local context (2) Minimize infrastructure impacts (3) Reduce air pollution	Education and employment (1) Improve local training and workforce development (2) Access to health care	Capital improvements (1) Develop infrastructure in surrounding communities (2) Generate additional tax based revenue for local community	(1) Achieve lasting economic and social benefit (2) Optimize system of learning and education (3) Expand and enable cooperative network
Ecology	Mitigate Disturbed Areas (1) Mitigate wetland impacts (2) Incorporate open space (3) Minimize negative impact on habitat	Conserve and protect natural systems (1) Monitor sensitive species (2) Preserve wild life corridors (3) Improve natural hydrology (4) Landscape with native plants	On-site restoration (1) Regenerate native systems (2) Restore native species in wildlife corridors (3) Coral reef propagation (4) On-site and off-site reforestation	(5) Maximise biodiversity and restore when necessary (6) Model on ecosystem, Biomimicry at macro and micro scale (7) Appropriate use of environmentally sound technologies
Energy	Efficiency (1) Reduce carbon emission (2) Energy efficient appliance (3) Building-scale energy demand reduction strategies (4) Promote public transportation	Active high performance system (1) Application of renewable energy systems (2) Transit- oriented development (3) Energy monitoring systems (4) Promote passive energy design	Renewable energy generation (1) Photovoltaic cells (2) Wind power (3) Zero emission transportation (4) Carbon sequestration	Carbon Zero (1) Continually minimize energy use through aggressive auditing
Water	Water efficiency (1) Water conservation (2) Xeriscaping (3) Low impact development	Water reclamation (1) Grey water recycling (2) On-site waste water treatment (3) Retaining water on-site	Water reuse (1) Onsite rainwater harvesting (2) Use of water recovery systems (3) Ground water recharge	Water balance (1) Effective demand management (2) Strive for net zero use (3) Match pre-development hydrologic conditions
Materials	National material sourcing (1) Active recycling (2) Reduce toxic materials	Regional material sourcing (1) Active reuse of materials (2) Onsite composting	Local material sourcing (1) Design consideration (2) Onsite agricultural production	(1) Minimize ecological footprint through construction and operations (2) Minimize waste production and promote responsible recycle and reuse

Along with technical challenges, this kind of integration enables a softer approach that helps to bring in opportunities to celebrate the human experience of making greener, healthier, more beautiful and more efficient communities. This multidimensional approach has the potential to weave in together different priorities and requirement to achieve design synergies and cost savings. This holistic design process makes it possible to rethink on alternative approaches using fundamental building science and material technology concepts that will be distinct, and can be appropriate and effective for different, geography, climate and culture. With this background the subsequent sections of the paper will highlight on building materials that has different energy impacts in different context and the transitions of vernacular communities with respect to adoption of conventional modern building engineering practices.

Responsible Selection of Building Materials: Significant Impact on Energy Efficiency of Buildings

Construction, operation and maintenance of buildings consume the largest energy, while globally accounting to one third of the world's resources (Atkinson, 1994). including approximately one third of primary energy supply with maximum ecological footprint (Pulselli *et al.*, 2007). The general breakup of energy consumption in buildings globally is 16:84, the former being the percentage attributed to manufacturing, construction material transport, and maintenance and renovation of a building, while the latter includes the energy share attributed to appliances and space conditioning and operation. (WBCSD, 2008) Manufacture of materials for building sector attributes to 20%–25% of India's total energy demand (Sanyal *et al.*, 2009). It is crucial to note that these estimates are related primarily to highly developed urban areas.

Careful selection of environmentally sustainable building materials is the easiest way to begin incorporating environment friendly design principles in buildings. Retrofitting buildings for energy-efficient performance can yield significant result in regulating Greenhouse Gas (GHG) emissions (Levine *et al.*, 2007). Cost of material has been the primary guiding factor for choice of specific building material. The market price of a building component represents only the manufacturing and transportation costs, while ignoring the social or environmental costs. Past studies on cost effective technology and low energy materials have attributed five modes of energy consumption to buildings; energy for extraction of material, energy for transport, energy for construction, energy for operation and maintenance, and finally energy for the demolition, and recycling or disposal (Sengupta, 2008). This is referred as the 'embodied energy' of a material.

A life cycle cost analysis of building products, from the gathering of raw materials to their ultimate disposal, provides a better understanding of the long-term costs of materials, which is paid not only by the owner, but also by the environment. Each step of the manufacturing process, from extraction of raw materials, manufacturing, distribution, and installation, to ultimate reuse or disposal, is examined for its environmental impact. This principles of Life Cycle Design provide important guidelines for the selection of building materials. A material's life cycle can be organized into three phases: Pre-Building; Building; and Post-Building. These three life-cycle phases relate to the flow of materials through the life of the building (see Fig. 4).

Building materials are to be selected based on these three building phases. With respect to Pre-building phase the selection of materials should be based on reduction of waste, pollution prevention, recycled content of the materials and reduction of embodied energy. The primary considerations for selection of materials with respect to Building phase is reduction in construction

Fig. 4 Three phases of the building material life cycle. Adopted from Kim, J.J., Rigdon, B., 1998. Sustainable Architecture Module: Qualities, Use, and Examples of Sustainable Building Materials. Ann Arbor, MI: National Pollution Prevention Center for Higher Education.

Table 2 Energy and environmental effectiveness

Initial embodied energy per m ³ of wall		Pollution emission (kg of CO ₂) per m ³ of wall	
CSEB wall	631 MJ/m ³	CSEB wall	56.79 kg/m ³
Kiln Fired Brick (KFB)	2,356 MJ/m ³	Kiln Fired Brick (KFB)	230.06 kg/m ³
Country Fired Brick (CFB)	6,358 MJ/m ³	Country Fired Brick (CFB)	547.30 kg/m ³

Source: Building with Earth, Auroville – Earth Institute.

waste, energy efficiency, use of non-toxic or less-toxic materials, and durability. Reusability, recyclability, biodegradability characteristics of materials are important for the Post-building phase.

Life Cycle Analysis (LCA) is the tool to measure the environmental performance of a particular building material, which provide-

- Comprehensive understanding of its environmental impact
- Improvement ideas that can be offered at each stage in the life cycle of a material
- Decision system to compare and select materials
- Efficient alternatives and qualitative judgments to choose based on environmental and economic performance.

Life Cycle Cost (LCC) estimate apply

- Method to assess the cost effectiveness of a material
- Set of techniques to evaluate the present value of the asset over its operating life including initial capital cost, operational cost and the cost of salvage value.

The presence of certain features in building materials based on the material life cycle make it environmentally sustainable. The recycled content of a material reduces the waste stream and the demand on virgin natural resources. By recycling materials, the embodied energy they contain is preserved. Aluminum, for example, can be recycled with only 10%–20% of the energy that is required to transform its raw ore into finished goods. Glass, plastics, metals, concrete or brick, and wood have potential for recycling. Reduction of embodied energy of material by revision of manufacturing process reduces the amount of energy required to produce it, implying less ecological consequences.

Minimization in use of natural resources by minimizing resource quantity through optimization of quantity of materials used for building can also give good result. This can be achieved by building less, such as reducing wall thickness and optimized utilization of built spaces. Examples of reducing embodied energy by replacing conventional materials are; replacement of cement in concrete with coal fly ash or ground granulated blast furnace slag, use of lime pozzolana mortars in place of cement mortars, soil or stabilized soil blocks over burnt clay bricks, light weight concrete blocks over dense concrete blocks, gypsum plaster over cement plaster, load bearing masonry in place of framed structure wherever possible.

Researchers around the world are working on new scientific ideas and techniques to improve the strength and durability of structures made of earth. Use of Compressed Stabilized Earth Blocks (CSEB) and Rammed Earth construction are being promoted across the world. Use of locally available natural materials are generally lower in embodied energy and toxicity than man-made materials (Table 2).

Use of energy efficient materials is an important selection criteria for making the building environment responsive. The long-term energy costs of operating a building are heavily dependent on the materials used in its construction. The energy-efficiency of building materials can be quantitatively measured using factors such as R-value (Resistance), shading coefficient or Solar Heat Gain Coefficient (SHGC), U-value (Transmittance), thermal conductivity, luminous efficiency, or fuel efficiency. Effective selection of materials reduces the transfer of heat through a building's envelope and consequently reducing the need for heating or cooling. Quantitative measurements of a building material's efficiency are available to help in the comparison of building materials and determining appropriateness for certain installations. The shading coefficient (SC) or SHGC comparatively evaluates the sun-blocking effectiveness of various glass types, shading devices, and glazing patterns. Past literature also suggests that energy related environmental impacts on buildings is to be considered through their life-cycle and environmental analysis by focusing on factors that influence energy consumption. Evaluation of building envelope, glazing and fenestrations, thermal mass and insulation of buildings, daylighting and artificial lighting, natural versus mechanical ventilation, energy-recovery opportunities, indoor and outdoor air quality and environmental protection (Todorovi, 2019).

Environmental Impacts of Transition in Rural Settlement

Architectural Design is a complex art, rooted in strong intellectual, cultural and spiritual traditions, but also modified through technological development and intelligent application (Bundgaard, 2011). The inevitability of change and dynamism attributed to the built environment must be recognized within the discourse on responsible design principles. Rural areas are undergoing transformation while responding to the modernizing aspirations of its inhabitants. Significant transitions in the rural fabric has brought about a paradigm shift in the theology of traditional building practices. Traditional building practices used to adhere to the physical and metaphysical context of the place it belonged to and suited to the social, cultural and environmental need of the

inhabitants. The performance evaluation of such buildings would rank high in the efficiency index, considering the four aspects; self-built or community-built, use of local resource for materials, utilization of traditional technologies and synergy with environmental context.

It has been found that there exist a significant relation between the community's lifestyle and environmental sustainability (UNCHS, 1990). The so called 'Development' of traditional settlement meant to describe the human act of improving, or attempting to improve well-being is being recently examined from different directions; as indicating fading culture (Mani and Reddy, 2012), contested lifestyles, sustainability issues and environmental impacts. Steadily changing pattern of actions, rules, values and norms have altered the traditional ways of life, which has impacted the environmental quality of vernacular settlements. Modern aspirations are resulting in transitions from low energy local resource dependent habitations to energy intensive non-local resource based modern style habitations. Further, these transitions are resulting in the habitations becoming increasingly unsuited to the local climatic conditions with increasing discomfort and environmental disruption. It is estimated that adoption of modern building materials in rural dwellings have a clear potential to increase GHG (Greenhouse Gas) emission between 8.5 and 10% of projected 2031 national emissions of India (MoEF, 2009).

Recent ideologies of zero-energy and low carbon footprint much advocated as means to achieve sustainability in urban areas are intrinsic practices in vernacular settlements, as they are less dependent on active energy systems. Only 60.2% of rural households use electricity as the primary source of lighting. Energy requirement for thermal comfort is negligible, as the vernacular dwellings have incredible ability to passively regulate the indoor environment to achieve thermal comfort. The building materials used are less energy intensive and community led construction activity is adopted.

Studies on rural transition in India have found that the roofs of vernacular dwellings have undergone significant transformation. It was seen that within 15 years the use of Reinforced Cement Concrete (RCC) roofs was on the rise, along with Asbestos Corrugated (AC) sheets or Galvanised Iron (GI) corrugated sheets, as well as houses with a combination of old and new roof types and materials have increased by almost 50%. They found that this transition was due to the aspiration to live in a safe and maintenance free house, and it has resulted in less thermal comfort with 7–10°C rise in indoor air temperature during summer. All the criteria of well-being could not be achieved as there was less satisfaction from meeting physical, mental and environmental needs.

A study conducted in the heritage village of Raghurajpur in Odisha, shows that over the past decade transitions in their dwellings, is primarily seen in the building materials adopted, while building layout still remain the same. The community lived on minimum resource for basic survival within the natural setting of the village with negligible demands on energy and process-intensive materials for sustenance. Earlier building materials used were mud, bamboo, thatch, laterite stone blocks and bricks, which were locally available. Walls and attic roof of some of the houses which still exist used wattle daub construction, where mud reinforced with bamboo and wooden twigs is used as a composite material, which is made by the community in response to the prevalent climatic and environmental conditions (Fig. 5). These vernacular dwelling regulate the indoor thermal environment and provided adequate occupant comfort without the need of mechanical cooling system like fan.

The transitions can be observed in progressive phases, first phase involved the replacement of traditional thatch roof by either a corrugated asbestos cement or tin sheet roof; in the second phase burnt clay brick wall with mud mortar replaced traditional earthen walls; third phase, which is the present trend involves a total transition to burnt clay brick walls with cement mortar and corrugated tin sheet roof or reinforced cement concrete roof (Fig. 6). These transitions in the rural setting have altered the indoor and outdoor environmental conditions. The integration of concrete and asbestos roof in the traditional compact form of the dwelling, has resulted in the dwellings becoming increasingly unequipped to maintain comfortable indoor conditions. From the survey conducted in the village it was observed that there is unanimous response of increasing thermal discomfort within the altered dwellings and outside due to increased built footprints and reduction in natural environment.

The earthen structures of rural West Bengal which have evolved over generations use locally available building materials: thatch, earth and bamboo and constructed by the community. The built form, orientation, and preparation of materials all follow simple, well-established rules in response to local climatic conditions. Past studies shows that although the external diurnal

Fig. 8 Transformation of dwellings and use of modern construction materials. *Source:* Moothedath, C.K., Nallaval, C.B., Monto, M., 2015. Well-being and sustainable design: A case study of building typology transition in a rural settlement in India. In: Mani, M., Kandachar, P. (Eds.), Design for Sustainable Well-Being and Empowerment. IISc Press and TU Delft, 207–226.

temperature varies between 10 and 15°C, indoor temperature variations are maintained within 3°C, which is well within physiological resilience of the inhabitants (Mani and Reddy, 2012). Transformation in their dwellings is primarily in the use of modern building materials, like corrugated asbestos/cement (AC) sheet roofs (Fig. 7). Although the inhabitants agreed upon the indoor discomfort conditions, the community is still drawn towards adopting modernized methods of building construction.

The traditional building typology of the villages in Karnataka is characterized by a single-room space with a thatched roof, and very few roofs of stone slabs, walls constructed from adobe or sundried bricks or straw bamboo reinforced adobe, and floors plastered with cow dung or mud. Random rubble (RR) masonry and stone flooring with clay- tiled roofing are also in practice.

Fig. 9 Transition trend of vernacular roof. *Source:* Moothedath, C.K., Nallaval, C.B., Monto, M., 2015. Well-being and sustainable design: A case study of building typology transition in a rural settlement in India. In: Mani, M., Kandachar, P. (Eds.), *Design for Sustainable Well-Being and Empowerment*. IISc Press and TU Delft, 207–226.

Similar to the first two cases the aerial picture of the area reflect the increase in built-spaces of the villages as well as the transition of the roof materials. The use of Reinforced Cement Concrete (RCC) roofs is on the rise, along with Asbestos Corrugated (AC) sheets or Galvanised Iron (GI) corrugated sheets, as well as houses with a combination of old and new roof types and materials (Figs. 8 and 9).

Conclusion

Instilling environmental ethics and responsibility for sustaining the environment are means to recognize the place and make commitment to the natural environment. Across the world, in every sphere people are talking about ‘sustainability’. For varied reasons, though there is wide usage of the very term, yet the true understanding of the term ‘sustainability’ is often not reflected in the day to day practices done by the people. Building activities are a major contributor to the world’s total pollution. Talking about ‘Sustainable’ Buildings is no more enough in handling the burgeoning environmental pollution issue. As a human being, since our childhood we grew up with certain universal values and we are taught to become responsible. Are we behaving very responsibly as an user or as an architect in the society? The aim of this paper is not to provide any toolkit or database rather opening up an agenda for further discussion in order to create avenues for further research leading to policy framing in future.

“There is, it seems to us at best, only a limited value in the knowledge derived from experience.

The knowledge imposes a pattern, and falsifies, for the pattern is new in every moment is a new and shocking valuation of all we have been”. -T.S. Eliot

Thermal Insulation of Buildings

The twenty-first century's challenge for energy and environmental efficiency of buildings requires the thermo-hygrometric characteristics of the building envelope to be adequate to the climate, in order to guarantee the best thermal comfort for the inhabitants with the lowest energy consumption and greenhouse gas emissions. Space heating and cooling account for over 30% of all energy globally consumed in buildings, rising to as much as 50% in cold climate countries. In the residential sector, the share of energy consumption used for heating and cooling in cold climate countries is over 60% (IEA, 2015).

Therefore, the goal to achieve buildings with very high energy performance, characterized by a very low or almost zero annual energy requirement, has made it essential to provide, with specific insulation materials, an adequate thermal insulation of the walls, roofs and floors of new and existing buildings in order to reduce heat losses in winter and heat gains in summer.

Research and development on insulation materials are now focusing on two main areas. On the one hand, the increasingly important goal to promote the use of environmentally friendly building materials and products is leading to the development of insulation materials with a lower environmental impact along the whole life cycle, preferring those rapidly renewable, of vegetable or animal origin, possibly recycled and recyclable, non toxic and with low energy production techniques (bio-based insulation materials).

On the other hand, the necessity of rapidly carrying out the energy renovation of the existing buildings stock is leading to a new class of high performance insulation materials able to guarantee the required thermal resistance with minimal thickness (nano-porous insulation materials – NIMs).

The choice of the most suitable insulation material depends on the type of application and the operating conditions. In addition to the thermal performances, insulation materials have now to be evaluated for other aspects such as limited impact on living space, acoustic behavior, fire reaction, compressive resistance and behavior in the presence of water and vapor. Resistance to damaging agents such as moisture and rodents should also be considered when relevant for the application.

The choice should also consider aspects like lightweight construction and ease of installation, competitive price, full compatibility with all relevant material combinations, enhanced durability for increased operative life, reduced maintenance and reduced costs.

Finally, particular attention must be paid to the life cycle sustainability of selected materials in terms of energy incorporated in the product, emission of substances harmful to the health and the environment, ease of deconstruction and reusability/recyclability at end of life, evaluated via specific life cycle assessment studies.

Classification of Building Insulation Materials

In building construction, we define as “insulation materials (or insulating materials)” those materials that show a thermal conductivity $\lambda \leq 0.065 \text{ W m}^{-1} \text{ K}^{-1}$ and that are consequently employed as functional layer to increase the thermal resistance, or R-value ($\text{m}^2 \text{ K}^{-1} \text{ W}^{-1}$), of the components of the building envelope.

The thermal behavior of insulation materials is explained by the fact that the base material occupies only a small part of their entire volume – as is shown clearly by the comparison between their apparent density and the density of the base material itself – while the rest is constituted by air. This, on the other hand, is distributed in pores or capillaries, arranged in many cavities so small as to exclude the presence of convective motions. The transmission of the pores is therefore to be attributed to the internal conductivity of the air, which, like all other gases, is modest at ordinary temperatures ($0.026 \text{ W m}^{-1} \text{ K}^{-1}$). Below are the values of thermal conductivity, density and specific heat of main construction materials (Table 1).

Based on their origin, either organic or inorganic, insulation materials are classified into 4 main categories (Table 2): vegetal (cork, wood fiber, hemp fiber, coconut fiber, etc.), animal (sheep's wool), mineral (glass fiber, mineral wool, expanded vermiculite, pumice, aerogel, etc.) or synthetic insulators (polyurethane, polystyrene, polyethylene foam, etc.).

The structure of insulation materials can be fibrous (mineral wool, wood fiber), porous (cork, expanded vermiculite, pumice) or cellular (polyurethane, polystyrene, polyethylene foams). These cavities may be intercommunicating (open cell insulators), as in the case of fibrous materials, or non-communicating (closed cell insulators), as in the case of synthetic insulators with cellular structure (expanded polystyrene or polyurethane).

Products available on the market can come in form of panels, rolls, mats, felt, bands, with different sizes and thickness from 5 to over 200 mm, or in bulk to be applied on site by blowing, injection or spraying. Depending on material, shape and application, insulating products can be installed by simply laying rolls, mats or fillers above roofs and floors, by fixing panels on walls or ceilings with adhesives, nails, screws or anchors, or by blowing beads, flakes or granules inside interspaces or attics.

Table 1 Thermal conductivity, volume mass and specific heat of main construction materials

Materials	Thermal conductivity ($W\ m^{-1}\ K^{-1}$)	Volume mass ($Kg\ m^{-3}$)	Specific heat ($J\ Kg^{-1}\ K^{-1}$)
Metals	420 ÷ 17	11300 ÷ 2700	880–380
Natural stones	4.1 ÷ 0.63	3000 ÷ 1500	1000
Plaster and mortars	1.40 ÷ 0.29	2000 ÷ 600	1000
Close structure concrete	1.16 ÷ 0.75	2000 ÷ 1700	1000
Open structure concrete	1.06 ÷ 0.13	1900 ÷ 250	1000
Glass	1	2500	750
Porcelain	1	2300	840
Bricks	0.90 ÷ 0.25	2000 ÷ 600	840
Waterproofing materials	0.70 ÷ 0.23	2100 ÷ 1100	1000
Compact plastic materials	0.50 ÷ 0.28	2000 ÷ 1050	2200–900
Water (calm at 293K)	0.6	1000	4190
Wood	0.22 ÷ 0.12	850 ÷ 450	1600
Cellular plastic materials	0.059 ÷ 0.032	80 ÷ 10	1450
Still air	0.026	1.025	1005

Table 2 Classification of main building insulation materials

Origin	Material	Structure			Available products
		Fibrous	Cellular	Porous	
Vegetable	Bagasse	■			Panels
	Cellulose fibers	■			Spray, blowing filler, panels
	Coir fibers	■			Panels, bands
	Cork		■		Filler, panels
	Corn fibers	■			Panels, rolls, mats
	Flax fibers	■			Panels, rolls, felt, bands
	Hemp fibers	■			Panels
	Jute fibers	■			Panels
	Kenaf fibers	■			Panels, rolls
	Mineralized wood wool	■			Panels
	Mushroom	■			Filler, panels
	Reed	■			Mats
	Rice hull	■			Filler
	Seaweed	■			Filler, panels
	Straw bale	■			Blocks
	Wood fiber	■			Panels
	Wood wool	■			Panels
	Sheep wool	■			Rolls, felt, bands
Animal	Natural pumice			■	Filler
	Expanded clay			■	Filler
	Expanded perlite			■	Panels, filler
	Expanded vermiculite			■	Filler
	Cellular glass		■		Panels
	Expanded glass granules		■		Panels, filler
	Silicate calcium			■	Panels
	Stone wool	■			Panels, rolls, mats
	Glass wool	■			Panels, rolls, mats
	Aerogel			■	Panels, rolls, mats
Synthetic	Sintered expanded polystyrene (EPS)		■		Panels
	Extruded expanded polystyrene (XPS)		■		Panels
	Expanded polyurethane (PUR)		■		Panels, spraying foam
	Expanded phenolic resins		■		Panels
	Expanded polyethylene foam		■		Panels, Rolls
	Polyester fibers	■			Panels, Rolls

Beyond this main classification, several insulation products available on the market are actually a combination of more materials, usually of different origin. These composite solutions are normally made of a main insulation material to provide the bulk of the thermal resistance, and additional materials to improve the mechanical characteristics (such as polyester fibers in sheep wool for reinforcement), as

Table 3 Thermal conductivity of main insulation material

Insulation material	Thickness (mm) for achieving $U = 0.25 \text{ W m}^{-2} \text{ K}^{-1}$	Thermal conductivity λ , $\text{mW m}^{-1} \text{ K}^{-1}$
<i>Innovative high performance products</i>		
Vacuum Insulating Panels	30	8
Aerogel	50–55	13–15
<i>Polyurethane (PUR)</i>		
Polyurethane with pentane up to 32 kg m^{-3}	105–115	27–30
Soy based polyurethane	100–145	26–38
Coated polyurethane with pentane up to 32 kg m^{-3} coated	75	22
Polyurethane with CO_2	130	35
On site applied polyurethane (sprayed/injected)	80–100	23–28
<i>Polyisocyanurate (PIR)</i>		
Polyisocyanurate up to 32 kg m^{-3}	95–105	25–28
Coated polyisocyanurate up to 32 kg m^{-3}	80–85	22–23
On site applied polyisocyanurate (sprayed/injected)	80–100	23–28
Polyisocyanurate up to 32 kg m^{-3}	95–105	25–28
Coated polyisocyanurate up to 32 kg m^{-3}	80–85	22–23
On site applied polyisocyanurate (sprayed/injected)	80–100	23–28
<i>Phenolic foam</i>		
Phenolic foam	80–95	20–25
Coated Phenolic foam	75–85	20–23
<i>Expanded polystyrene foam (EPS)</i>		
Expanded polystyrene foam up to 30 kg m^{-3}	115–165	30–45
Expanded polystyrene foam with graphite (grey)	115–120	30–32
<i>Extruded polystyrene foam (XPS)</i>		
Extruded polystyrene foam with CO_2	95–140	25–37
Extruded polystyrene foam with HFC 35 kg m^{-3}	110–120	29–31
<i>Mineral insulating materials</i>		
Glass wool	135–180	30–44
Rock wool up to 160 kg m^{-3}	150–170	34–40
Vermiculite	235	39–60
Cellular glass	140–185	38–50
Expanded perlite panels	190	51
<i>Bio-based insulating materials</i>		
Cotton	165–170	39–40
Cork 120 kg m^{-3}	155–200	41–55
Wood fiber	145–225	39–61
Sheep wool 25 kg m^{-3}	150–215	34–54
Injected cellulose fiber 24 kg m^{-3}	150–190	35–46
Hemp fiber	165	39

binders (such as cement in mineralized wood fibers), to form a support matrix (FRABs) or to convey desirable properties such as resistance to fire (via fire retardant additives) or to water (with a bitumen or fiberglass sheet) or vapor tightness (with aluminum foils).

Thermal Properties

Thermal conductivity (λ) values of most common insulation materials available on the market typically range from 0.032 to $0.045 \text{ W m}^{-1} \text{ K}^{-1}$. Best performance can currently be achieved with EPS boards integrated with graphite with a thermal conductivity of $0.030 \text{ W m}^{-1} \text{ K}^{-1}$ (20% lower than conventional EPS) and with PUR foams that go as low as $0.022 \text{ W m}^{-1} \text{ K}^{-1}$, or with advanced nanoporous insulation products such as vacuum insulating panels or aerogels that allow to reach λ values lower than $0.015 \text{ W m}^{-1} \text{ K}^{-1}$ (Table 3).

The thermal resistance (R) of a homogenous layer of insulation material of thickness (d) can be calculated by the expression:

$$R = \frac{d}{\lambda} \left[\frac{\text{m}^2 \cdot \text{K}}{\text{W}} \right] \quad (1)$$

in which:

R = thermal resistance ($\text{m}^2 \text{ K W}^{-1}$)

d = thickness (m)

λ = thermal conductivity ($\text{W m}^{-1} \text{ K}^{-1}$)

Fig. 1 Knudsen effect in nanoporous insulators. Reproduced from Casini, M., 2016. Smart buildings: Advanced materials and nanotechnology to improve energy-efficiency and environmental performance. Cambridge: Woodhead Publishing Limited.

Envelopes of existing buildings without thermal insulation materials show on average thermal resistance values (R) comprised between 0.28 and 1.00 $\text{m}^2 \text{K W}^{-1}$ in relation to thickness, constituting materials and the presence of any air gap. Current European standards oriented to the achievement of zero energy buildings require, in relation to the climate area, minimum values comprised between 2.22 and 5 $\text{m}^2 \text{K W}^{-1}$, making the use of insulation materials absolutely necessary. According to (IEA, 2015), 6 centimeters of a conventional insulation material with a thermal conductivity of 0.030 $\text{W m}^{-1} \text{K}^{-1}$ are able in fact to provide by themselves a thermal resistance of 2 $\text{m}^2 \text{K W}^{-1}$, whereas more than 1.5 m of bricks ($\lambda = 0.75 \text{ W m}^{-1} \text{K}^{-1}$) are required to achieve the same performance.

Recent advancement in the development of insulation materials is due to the progress in nanotechnology and material sciences, and has allowed to obtain high performance thermal insulators (HPTIs) with a thermal conductivity well below 0.020 $\text{W m}^{-1} \text{K}^{-1}$, making them particularly suitable for energy retrofit interventions. Such performance is achieved thanks to the higher rarefaction of air inside the insulation materials due to their nanoporous solid structures. These nanotechnological insulating products are made of aerogel (air + gel), a solid nanoporous material with ultra-low density obtained through the dehydration of a colloidal gel by replacing the liquid component with a gaseous one, integrated in a fibrous support structure (Fiber Reinforced Aerogel Blankets – FRAB).

In nanoporous materials such as aerogel, high porosity reduces heat conduction through the solid part, while the small size of the pores, typically ranging from 5 to 100 nm and an average pore diameter between 20 and 40 nm, reduces the radiation and the conduction in the gas. By reducing the pore size to nanoscale level, air molecules collide with the pore walls more often than with each other dispersing most energy within the porous structure (see Fig. 1) leading to suppressed gas conduction (Knudsen effect) and to thermal conductivity values typically of 0.015 $\text{W m}^{-1} \text{K}^{-1}$.

The values of thermal conductivity indicated in the product sheets of insulation materials are usually calculated at a temperature of 10°C. However, the thermal conductivity is greatly affected by the actual temperature of the material, which, in summer, can easily exceed 50°C when exposed to the outside. It is therefore important to know, in relation to the methods of application, the actual performance of each material at the operating temperature, as the increased mobility of air molecules inside porous, fibrous or cellular materials usually decreases thermal resistance. From this point of view, Fiber reinforced Aerogel blankets present, compared to all other insulation materials, a constant thermal performance regardless of operating temperature (Fig. 2).

Concerning the growing importance of the building behavior in the summer period, in addition to the thermal conductivity parameter, a further parameter useful to characterize the performance of the insulation material in a dynamic regime, in order to delay and dampen the incoming thermal wave and to reduce the phenomena of overheating of internal environments is that of thermal diffusivity (a), obtained from the relation:

$$a = \frac{\lambda}{\rho \cdot c} \left[\frac{\text{m}^2}{\text{s}} \right] \quad (2)$$

in which

a = thermal diffusivity ($\text{m}^2 \text{s}^{-1}$)

λ = thermal conductivity ($\text{W m}^{-1} \text{K}^{-1}$)

ρ = density (kg m^{-3})

c = specific heat ($\text{J kg}^{-1} \text{K}^{-1}$)

This parameter allows to take into account not only the insulating properties, but also those of heat accumulation in a certain volume of material. The lower the diffusivity of a material, the quicker and for short distances it will extinguish the thermal wave produced on its surface. Given an equal thermal conductivity, the insulators that behave better in the summer are those that have

Fig. 2 Thermal conductivity of insulation materials related to operating temperature. Reproduced from Reproduced from Casini, M., 2016. Smart buildings: Advanced materials and nanotechnology to improve energy-efficiency and environmental performance. Cambridge: Woodhead Publishing Limited.

high values of specific heat and density. From this point of view, a good behavior in summer characterizes insulators such as mineralized wood fiber, cork and high density mineral wool (Table 4).

Application and Comparative Analysis

The choice of the type of material or product to use for the thermal insulation of a building and the related methods of installation depends on numerous factors including, in particular:

- The type of building intervention, whether new construction or renovation, on which depend the possibilities of application in terms of compatibility of materials, installation methods and thicknesses allowed;
- The technological unit of the affected building (vertical closure, horizontal closure, etc.) and the functional model of the technical element (external insulation, internal insulation, interspace, ventilated wall (see Fig. 3), which determine the minimum performance that the insulation must guarantee, the categories of suitable insulators and the related application technologies;
- The operating conditions (external climatic conditions, exposure to atmospheric agents, thermo-hygrometric values of the environments, loads, exposure to fire, available space, etc.) on which depend the performance that the insulation must provide;
- The environmental sustainability objectives that are to be achieved with the intervention and with the materials and products used.

As consequence, parameters for selection concern (Hilla *et al.*, 2018; Adityaa *et al.*, 2017):

- Thermo-hygrometric behavior (thermal conductivity and thermal diffusivity);
- Behavior in the presence of water (imbibition coefficient) and resistance to vapor diffusion (water vapor diffusion resistance factor);
- Mechanical behavior (compressive strength);
- Fire reaction, including the possible emission of fumes and toxic substances during combustion (Euroclass);
- Acoustic behavior (weighted sound reduction index, sound absorption coefficient);
- Ease of installation and workability on site, including dust emissions during processing;
- Durability, including resistance to biological agents, insects and rodents;
- Cost to obtain a given thermal resistance;

- Environmental sustainability of the life cycle, in terms of energy incorporated into the product (embodied energy), renewability and recyclability of the material, content of recycled material in the product, absence of release of hazardous substances during processing and use, etc.

The embodied energy indicates the non-renewable energy used to transform raw materials into building products, measured in energy per mass unit (MJ kg^{-1}) or, for insulation materials, in energy per surface unit with a given thermal resistance (MJ m^{-2}). It refers to overall energy consumed during raw materials acquisition, transportation to the factory, transformation into finished products. Insulators of animal and vegetable origin, with the exception of cork and mineralized wood fiber, are those with the lowest embodied energy values, whereas highest values characterize insulators of synthetic origin (Table 4).

Fig. 3 Perimeter wall insulation functional models.

Table 5 Suitable insulation products for different building envelope functional models

Functional model	Suitable insulation products
Wall with outside insulation (ETICS)	Panels with high rigidity to allow the application of sheet cladding or external plaster (External Thermal Insulation Composite System – ETICS). Insulation materials of synthetic origin (polyurethane, polystyrene, expanded polyethylene, aerogel) or closed cell vegetables (cork), which can also offer greater water resistance. Mineral wool panels with increased density and mechanical resistance are also suitable to allow greater passage of vapor.
Wall with interspace insulation	Panels, or rolls, of all types, or loose materials (cellulose flakes, granulated perlite and expanded vermiculite, cork granules) poured or blown with specific tools. Recommended products are panels or rolls with open cells, loose fillers.
Wall with inside insulation	Panels, or rolls, of all types (synthetic, mineral, vegetable and animal) with the application of gypsum wall boards, fiberboards or cement panels. Open cell types are the most suitable, with FRABs recommended for intervening on existing buildings to minimize loss of floor area.
Ventilated and insulated wall	Closed cell panels or ETICS compliant mineral wool panels
Insulated flat roof	Materials with high compressive strength, such as extruded polystyrene (XPS), polyurethane foam (PUR), mineralized wood fiber, FRABs.
Inverted flat roof	Waterproof and weather resistant materials such as extruded polystyrene (XPS) or polyurethane (PUR) in panels of a smaller size, or FRABs.
Pitched roof	All types of insulating rolls or panels. In case of ventilated roofs, open cells insulators are recommended to allow free vapor flow from the inside.
Green roof	Closed cell materials with high compression resistance such as extruded polystyrene (XPS) or polyurethane (PUR).
Interfloor slab with acoustic insulation	Thin layer of fibrous materials able to absorb the vibrations passing through and convert them to heat, such as coir, kenaf, polyester fibers.

Open cell, porous or fibrous insulators (expanded melamine resin, wood fiber, stone or glass wool) exhibit higher thermal conductivity and poor behavior in presence of water, but on the other hand perform better in terms of possibilities of acoustic insulation of the building, offering a greater resistance to the passage of noise, and of breathability, making them particularly suitable for the insulation in cavity walls and for the insulation of pitched roofs (Table 5).

XPS is the insulation material that has the highest compressive strength values and is therefore recommended to insulate floors that have to withstand high loads. Mineral wools are the insulators that present the best fire behavior and are therefore used also for building fire closures. Closed cell synthetic insulators such as EPS, XPS and PUR have the best water behavior and therefore suitable for applications exposed to atmospheric agents (ETICS, ventilated walls, inverted roofs). Insulators such as cork, coir or wood fiber are instead used as a thin mats for the reduction of walking noise in inter-floor slabs.

FRAB's, as well as offering greater thermal insulation values ($\lambda = 0.015 \text{ W/mK}$) with a constant thermal performance regardless of operating temperature, compared to conventional insulation materials, show the following main advantages: high hydrophobicity values with high vapor permeability; low flammability (Euroclass C to A2); mould proofing, UV and weather resistance; ease of installation thanks to their lightness and ease of adaptation; ease of handling and storage. In view of these advantages, aerogel insulation materials' cost per square meter is however still high, about 8–10 times higher than traditional insulation, whereas the most economical insulation materials on the market are actually mineral wools and sintered expanded polyester (EPS).

Sustainability

Sustainability of insulation materials, as for all building products, must be evaluated through the analysis of their impact on health and on the environment throughout the entire life cycle (from cradle to cradle), from the acquisition of raw materials, through manufacture, transport, and use until their disposal (see Table 6 and 7). Green building designers are increasingly focused on choosing environmentally friendly products, certified (Eco-label) or with environmental product declaration (EPD), supplied by

Table 6 Life cycle sustainability features of insulation materials

<i>Life cycle stage/Environmental risk factors</i>	<i>Sustainable features of insulation materials</i>
<i>Raw materials supply</i> ● Consumption of non-renewable natural resources ● Land deterioration ● Pollution from transport	<i>Designed for resource and environment conservation</i> ● Renewable or vastly available raw materials ● Recycled or recovered raw materials ● Environment and biodiversity protection ● Use of natural techniques ● Certified cultivation and extraction systems
<i>Manufacturing process and distribution</i> ● Energy consumption due to manufacturing process, transport and distribution ● Air, water and soil pollution ● Health risks for production workers	<i>Designed for cleaner production and for efficient distribution</i> ● Absence of hazardous raw materials ● Certified environmental management system (EMAS, ISO 14001, ISO 50001) ● Low energy consumption in the manufacturing phase ● Low pollutant emissions ● Absence of risks for production workers ● Low distance from the construction site to the manufacturing plant (km 0)
<i>On-site works and installation</i> ● Harmful emissions during handling ● Production of procession scraps and waste	<i>Designed for easier and cleaner installation</i> ● Absence of harmful emissions hazards ● Ease of installation and workability on site ● Instructions for on-site operations and installation
<i>Building operation</i> ● Short and long term hazardous emissions ● Low durability of performance ● Low resistance to atmospheric and biological agents	<i>Designed for green use and maintenance</i> ● Absence of harmful emissions hazards ● High durability ● High resistance
<i>Decommissioning</i> ● Partial or total loss of natural resources following the impossibility to reuse, recover, recycle or reintroduce materials to the environment. ● Air, water and soil pollution for disposal	<i>Designed for re-use, re-manufacture, disassembly, recycling, safe disposal</i> ● Use of recyclable materials ● Ease of disassembly ● Absence of additives or substances that impede recycling ● Ease of treatment and disposal

companies holding an ISO 14001 or EMAS certificated environmental management system, or finally that participate on an extended producer responsibility program or are directly responsible for extended producer responsibility. The objective of construction sustainability also requires the designer to focus towards the use of local materials and products (so-called zero km material), in order to reduce the environmental impacts due to the transport to the building site.

While selecting building insulation materials in view of the sustainability, it is important to remind that there are no ecological materials in an absolute term, as the life of a building component is inextricably linked to the life of the building, influencing and in turn being influenced by it. The overall sustainability of the life cycle of insulation materials is therefore dependent on the distance between the place of manufacture and that of installation, on the characteristics of the context in which the intervention will be carried out, on the application methods of the product into the building, on the use conditions and on the method of disposal. For instance, the real possibility of recovering insulation materials is linked to not only the recyclability of the single products, but also to the construction techniques used and the method of demolition at the end of the building life. All these variables are not known to the scale of the product, and are definable only from time to time on the basis of the context and building characteristics and of the project requirements.
